Abstract—Three-level neutral-point-clamped (NPC) inverters are very appropriate for high-power adjustable-speed drive applications. Direct torque control is characterized by the merits of fast response, simple structure and strong robustness to motor parameters variations. This paper presents a 3-level inverter-fed direct torque controlled (DTC) induction motor (IM) drive based on optimized switching table. The problems of high voltage jump, smooth vector switching and neutral point balance are investigated and solved by introducing appropriate intermediate vectors. Furthermore, a speed-adaptive flux observer is employed to enhance the performance of the system by estimating the state variables including the stator flux and state current. Large starting current, which can occur in conventional DTC drives, is controlled effectively by introducing pre-excitation of the stator flux. Both simulation and experimental results are presented to verify the effectiveness of the proposed schemes introduced in this paper.

I. INTRODUCTION

Three-level inverters have become widespread in high-power industrial applications since they were first proposed by Nabae in 1981 [1]. Compared to 2-level inverters, they have better performance in terms of lower voltage stress across the semiconductors, less harmonic content and lower switching frequency [2]. Direct torque control (DTC) is a kind of high performance control strategy characterized by fast torque response, simple structure (without complicated rotary transformation) and strong robustness against motor parameter variation. Three-level inverter-fed DTC motor drives are very attractive in high power applications because they combine the merits of both 3-level inverters and DTC.

Most papers [3-4] related to DTC concentrate on 2-level inverters; there are few papers related to 3-level DTC [5]. To make 3-level DTC practicable, an appropriate vector should be selected to maintain the neutral point voltage balance and avoid high voltage jump. The principles of a commercial 3-level DTC adjustable speed drive (ASD), as manufactured by ABB, was introduced in [6]; however, there were undesirable high voltage jumps in the line voltage. To reduce the oscillation in the flux and torque, an LC filter was employed which increases the complexity of flux observation. Ref [5] improves the low speed performance of the 3-level DTC by applying the correct intermediate voltage; however, the problems of voltage jump and neutral point balance were not addressed.

This paper focuses on the problems of voltage jump and neutral point balance by incorporating an optimized switching table. To improve the low speed performance, a speed-adaptive flux observer is employed to estimate the stator flux, electromagnetic torque and rotor speed over a wide speed range. There is usually large starting current in conventional DTC [7] schemes and this paper solves this problem by introducing the pre-excitation of stator flux. The proposed schemes are simulated and experimentally verified.

II. DTC FOR 3-LEVEL INVERTER

A. Basic Principle of DTC

The mathematical model of an induction motor described by space vectors in a stationary frame by the following set of equations:

\[
ui = R_i i + \rho \psi, \quad (1)
\]

\[0 = R_i i + \rho \psi - j \omega \psi, \quad (2)
\]

\[\psi = L_s i + L_m i, \quad (3)
\]

\[\psi = L_s i + L_m i, \quad (4)
\]

where \(u_i\), \(i_i\), \(\psi_s\), and \(\psi_r\) are the stator voltage vector, stator current vector, stator flux linkage vector, rotor flux linkage vector, respectively; \(R_s\), \(R_r\), \(L_s\), \(L_m\) and \(N_p\) are the stator resistance, rotor resistance, stator inductance, rotor inductance, mutual inductance and motor pole-pair number; \(\omega\) is the rotor speed.

From the stator voltage equation (1), it can be seen that, by omitting the stator resistance voltage drop, the stator flux can be controlled directly from the stator voltage. This is a crude analysis and may cause error at low speed.

The electromagnetic torque can be expressed as

\[T_e = \frac{3}{2} N_p \frac{L_m}{\sigma L_s L_r} \|\psi\| \|\psi\| \sin \delta_{\psi}, \quad (5)
\]

where \(\delta_{\psi}\) is the spatial angle between stator flux and rotor flux and \(T_e\) is the electromagnetic torque. In the DTC, the amplitude of the stator flux is kept constant and a fast torque response is obtained by changing angle \(\delta_{\psi}\) quickly. From (1)-(4), the relationship between the stator flux and the rotor flux can be obtained from
\[ p\psi_r + \left(\frac{1}{\sigma T_f} - j\omega_r\right)\psi_r = \frac{I_{m}}{\sigma L_s T_f}\psi_r, \]  

where \( \sigma = 1 - \frac{L_m}{(L_s L_r)} \) and \( T_f = L_r / R_r \). Eqn. (6) indicates that the dynamic response of the rotor flux is a first-order lag with respect to the stator flux, so the torque can be changed quickly by changing the angle of stator flux.

### B. Vector Selection and Switching

For a 2-level DTC, the sector division and vector selection methods are relatively mature. However, for a 3-level DTC, because of the increased number of vectors, vector selection is more complicated, and in this paper we will solve the problem step by step.

Firstly, the vector is selected according to the demand of flux and torque; vector switching and neutral point balance will be considered later. Fig. 1 shows the space vector diagram for a 3-level DTC control strategy and its sector division. There are 12 sectors and the shadowed area is the first vector, which is different from that of the conventional 2-level DTC. The basic principles of the vector selection are shown in Table I and these meet the demands of the flux and torque; vector switching and neutral point balance.

The final vector selection rules are obtained by considering the aspects introduced above, and the principles are summarized as follows:

**Step I:** select vector according to the demands for flux and torque, which are listed in Table I;

**Step II:** if the selected vector cannot meet the requirement of voltage jump and neutral point balance, an appropriate intermediate vector will be inserted, and principles for selecting the intermediate vector are:

1. Large vectors or middle vectors should be selected preferably to increase the utilization ratio of DC bus;
2. Middle vectors can switch to adjacent small vectors and large vectors freely;
3. Large vectors can switch to the small vectors in the same spatial orientation;
4. Small vectors can switch to zero vectors freely;
5. When small vectors are available, select the one which can meet the requirement of neutral point balance.

Using the steps above, an appropriate vector can be selected to meet the demand of flux and torque, as well as the requirement of voltage jump and neutral point balance, which ensures the safe operation of the 3-level inverter.

### C. Decreasing Starting Current

To decrease starting current and maintain sufficient starting torque, the scheme of pre-excitation of stator flux is proposed.
in this paper. The stator flux will firstly be established by applying an appropriate vector, and during the pre-excitation process, the starting current is sampled and when it reaches the limit, zero vectors will be selected to decrease the current, which acts in a bang-bang fashion. When stator flux enters the range of demand, the process of pre-excitation is terminated and motor can start with sufficient torque, because there is enough flux to produce torque.

III. SPEED ADAPTIVE FLUX OBSERVER

This paper adopts a novel speed adaptive flux observer with load torque observation and novel gains [8]. The mathematical model of observer is express as

\[ p \dot{i}_s = - \left( \frac{1}{\sigma r} + \frac{1}{\sigma L_s} \right) j \omega \dot{i}_s + \frac{1}{\sigma L_s} \dot{\psi}_s + \frac{1}{\sigma L_s} u_s + G_1 (\dot{i}_s - \dot{\psi}_s) \]

(7)

\[ p \dot{\psi}_s = - R_s \dot{i}_s + u_s + G_2 (\dot{i}_s - \dot{\psi}_s) \]

(8)

\[ \frac{d\hat{\omega}_s}{dt} = \frac{N_s}{J} (\hat{T}_e - \hat{T}_i) + K_u \left[ \Delta L_s \otimes (\lambda L_s \hat{\psi}_s - \dot{i}_s) \right] \]

(9)

\[ \frac{d\hat{T}_e}{dt} = -K_T \left[ \Delta L_s \otimes (\lambda L_s \hat{\psi}_s - \dot{i}_s) \right] \]

(10)

where \( \dot{i}_s \) and \( \dot{\psi}_s \) are estimated stator current, estimated stator flux, respectively. \( G_1 = -(g_{1s} + jg_{2s}) \) and \( G_2 = -(g_{2s} + jg_{2s}) \) are the observer gains. \( K_u \) and \( K_T \) are positive constant gains. This paper employs a novel observer gain [1] to improve the stability of observer and it is expressed as

\[ g_{1s} = 2b \]

(11)

\[ g_{2s} = 0 \]

(12)

\[ g_{2s} = b/(\lambda L_s) \]

(13)

\[ g_{3s} = 0 \]

(14)

where \( b \) is a negative constant gain.

IV. SIMULATION AND EXPERIMENTAL RESULTS

To validate the effectiveness of the proposed techniques introduced in this paper, a system is simulated then validated experimentally, and the results are presented here. Fig. 2 illustrates the arrangement of the sensorless 3-level DTC drive implemented. The parameters for the simulation and experiments are listed in Table II.

A. Simulation Results

Figs. 3 to 6 show the response of the 3-level sensorless induction motor drive, starting from 0 rpm and going up to 1500 rpm when unloaded. The stator flux is first established before \( t = 0.05 \) s by using the pre-excitation technique, which can be seen from the upper half in Fig. 3. Then the motor accelerates up to 1500 rpm with the permitted maximum torque. At about \( t = 0.18 \) s, the motor reaches the steady-state speed at 1500 rpm. A step load of 0.5 p.u. at \( t = 0.5 \) s is applied to test the robustness of DTC to an external disturbance. It can be seen in Fig. 4 that there is only a slight fall in speed and it returns to normal state quickly. This validates the excellent dynamic performance of the DTC. Fig. 5 gives the line voltage and voltage fluctuations at the neutral point while Fig. 6 shows the zoomed line voltage at 1500 rpm. The neutral point voltage is controlled well and the oscillation is kept to within the range of \( \pm 5 \) V. There is no high voltage jump in either the line voltage or phase voltage, which validates the effectiveness of the proposed optimal vector table and the principle of the vector selection procedure.
is floating and controlled as discussed in Section II. The TMS320F2812 is a fixed-point 32-bit DSP which is characterized by strong computation ability; it is very suitable for the digital control of a motor drive. The IQmath library and C language were utilized in order to obtain high precision and fast computation. There are many of peripheral resources in the DSP, including high speed AD conversion, two event managers (EVs) and sophisticated communication interfaces, etc. These facilitated the development of the motor control. A CPLD EPM7256AE was also incorporated into the control board to implement dead time, pulse management and to generate the final 12 triggering pulses. The DSP controller has a sufficient capacity in order to carry out the intensive computations, and it only needs 3.2 μs to fulfill the computation of the speed-adaptive observer. Fig. 7 illustrates the developed sensorless drive. The main circuits for the 3-level inverter, DSP control board and 2.2kW motor-generator are presented in Figs. 7(a), (b) and (c), respectively. Fig. 7(d) shows the 6RA70 controller, which is used to apply external load and implement 4-quadrant operation.

B. Hardware Implementation

An experimental prototype has been developed to implement the 3-level DTC drive. This has three parts: a 3-level inverter, an induction motor and a TMS320F2812 DSP-based control board. The neutral point of the 3-level inverter
The robustness to external disturbance was tested and the results are illustrated in Fig. 10. Full-load was applied to the sensorless drive and then removed. It can be seen that there was only a slight drop in the speed response before recovery, which confirms the robustness of DTC to external disturbance.

From Fig. 11 it can be seen that there is no high voltage jump in the line voltage, which proves that the proposed optimal switching table and the principles of the vector selection are correct.

Finally, low speed operation without and with load were tested. Fig. 12 shows the steady operation at 60 rpm. It is seen that the estimated speed exactly matches the real speed. The sensorless drive can work down to 30 rpm with full load, as illustrated in Fig. 13, which exhibits excellent performance in the low speed range.
V. CONCLUSION

A sensorless 3-level inverter-fed induction motor drive is presented in this paper, which incorporates an optimal vector table and a speed-adaptive flux observer. Some aspects, including voltage jump, neutral point balance and large starting current, are investigated to assess the practicality of the 3-level DTC. The principles of the vector selection procedures are established and the pre-excitation technique is proposed to decrease the starting current. Both the presented simulation and experimental results confirm the effectiveness of the proposed schemes.
