Detection of Nocturnal Hypoglycemic Episodes (Natural Occurrence) in Children with Type 1 Diabetes using an Optimal Bayesian Neural Network Algorithm

H. T. Nguyen, Senior Member, IEEE, N. Ghevondian, and T. W. Jones

Abstract—Hypoglycemia or low blood glucose is unpleasant and can result in unconsciousness, seizures and even death. It is a common and serious side effect of insulin therapy in patients with diabetes. HypoMon is a non-invasive monitor that measures some physiological parameters continuously to provide detection of hypoglycemic episodes in Type 1 diabetes mellitus patients (T1DM). Based on heart rate and corrected QT interval of the ECG signal, we have continued to develop Bayesian neural network detection algorithms to recognize the presence of hypoglycemic episodes. From a clinical study of 16 children with T1DM, associated with nocturnal hypoglycemic episodes (natural occurrence), their heart rates increased (1.03±0.242 vs. 1.082±0.298, P<0.06) and their corrected QT intervals increased significantly (1.03±0.086 vs. 1.060±0.084, P<0.001). The overall data were organized into a training set (8 patients) and a test set (another 8 patients) randomly selected. Using the optimal Bayesian neural network with 10 hidden nodes which was derived from the training set with the highest log evidence, the sensitivity (true positive) value for detection of hypoglycemia in the test set is 89.2%.

I. INTRODUCTION

RESULTS of the Diabetes Control and Complications Trial (DCCT) Research Group in 1993 [1] showed that intensive insulin therapy for a mean of six years (maintaining glycemic levels to a target HbA1c level of 7%) as opposed to conventional therapy (with resultant mean HbA1c level of 9%) significantly lowered the risk for retinopathy by 47%, nephropathy by 54% and for neuropathy by 60% [1-2].

However, episodes of hypoglycemia, especially at night, were common among people treated for T1DM, largely because usual insulin preparations do not adequately mimic the normal patterns of endogenous insulin secretion [2]. In the DDCT, patients assigned to intensive therapy experienced a threefold increase incidence of severe hypoglycemic episodes over those receiving conventional therapy [1,3]. In that report, severe hypoglycemic episodes are defined as those in which the patient required assistance to treat the event and had documented blood glucose levels less than 50 mg/dl (2.8 mmol/l). Thus hypoglycemia proved to be a limiting factor in achieving improved diabetes control.

Symptoms of hypoglycemia arise from the activation of the autonomous central nervous systems (autonomic symptoms) and from reduced cerebral glucose consumption (neuroglycopenic symptoms), some of the latter being potentially life threatening. Autonomic symptoms (e.g., tachycardia, palpitations, shakiness, sweating) are activated before neuroglycopenic symptoms (e.g., reduced concentration, blurred vision, dizziness). Autonomic symptoms may provide the initial indication of the presence of hypoglycemia and allow the patient to recognise and correct the ensuing episode [6].

Nocturnal hypoglycemia is particularly dangerous because sleep reduces and may obscure autonomic counter-regulatory responses, so that an initially mild episode may become severe. The risk of severe hypoglycemia is high at night, with at least 50% of all severe episodes occurring during that time [7]. Deficient glucose counter-regulation may also lead to severe hypoglycemia even with modest insulin elevations.

Recently, we have developed an optimal Bayesian neural network algorithm for the detection of hypoglycaemic episodes in T1DM children using physiological parameters. Using the data from 25 children with T1DM volunteered for the 4-hour glucose clamp study to provide 28 sets of physiological responses, we have found that hypoglycemic episodes in T1DM children can be detected non-invasively and continuously [8-9].

In this paper, we develop an optimal Bayesian neural network algorithm for the detection of natural occurrence of nocturnal hypoglycemic episodes in T1DM children using physiological parameters such as heart rate, corrected QT interval and skin impedance. Section II provides an overview of the method used for non-invasive and continuous detection of hypoglycemia. Section III presents the development and results of an optimal Bayesian neural network used for the identification of nocturnal hypoglycemic episodes in T1DM children. Section IV provides a conclusion for this study.

II. METHODS

A. Non-Invasive Hypoglycemia Monitor

There is a limited number of non-invasive blood glucose monitoring systems currently available but each has specific drawbacks in terms of functioning, cost, reliability and obtrusiveness. Recently, GlucoWatch G2 Biographer from
Cygnus Inc was designed to measure glucose levels up to 3 times per hour for 12 hours. The AutoSensor (the disposable component) which was attached to the back of the GlucoWatch monitor and adhered to the skin will provide 12 hours of measurement. The product used reverse iontophoresis to extract and measure glucose levels non-invasively using interstitial fluid. It had to be calibrated before each measurement period and required a two-hour warm-up period. It required costly disposable components, the gel pads must be replaced after each use, sweating might cause skipped readings, and the measurement had a time delay of about 10-15 minutes. As a result of these limitations this device is no longer available.

Intensive research has been devoted to the development of hypoglycaemia alarms, exploiting principles that range from detecting changes in skin conductance (due to sweating) to measurements, by glucose sensors, of subcutaneous tissue glucose concentrations (Pickup, 2000; Rebrin; 1999). However, none of these have proved sufficiently reliable or unobtrusive.

Although real-time continuous glucose monitoring systems (CGMS) are now available to give real-time estimations of glucose levels, these still lack the sensitivity to be used as alarms. For the MiniMed Medtronic (Northridge, CA) CGMS, the median error was reported as 10–15% at a plasma glucose of 4–10 mmol/l [10-12] and the low efficacy of CGMS (79.1% sensitivity) in detecting unrecognised hypoglycaemia has been confirmed [13]. For the Abbott Freestyle Navigator CGMS, the sensor accuracy was lowest during hypoglycaemia (3.9 mmol/l), with the median absolute relative difference (ARD) reported as 26.4% [14]. As these are median values, the errors may be significantly greater and, as a result, the manufacturers do not recommend their use as an alarm.

We have developed a continuous non-invasive hypoglycemia monitor which uses physiological responses [8-9]. HypoMon® (Hypoglycemia Monitor) from AlMedics Pty Ltd (Fig. 1) is a non-invasive monitor that measures physiological parameters continuously to provide detection of hypoglycemic episodes in Type 1 diabetes mellitus patients (T1DM). The system consists of a battery-powered chest belt worn that houses a set of four skin-surface biosensor electrodes for the measurement of physiological parameters and a hand-held receiver computer.

The sensors are composed of a conductive polymer-based material such as polypyrrole which has low impedance and low noise characteristics. These characteristics enable the sensors to measure both skin impedance and quality ECG signals. The chest belt digitizes, encrypts and transmits the measured parameters to the receiver computer which analyzes and identifies hypoglycemic episodes. An alarm system is available for warning various stages of hypoglycemia.

### B. Bayesian Neural Network

Bayesian neural networks were firstly introduced by MacKay as a practical and powerful means to improve the generalisation of neural networks [16-19]. Bayesian learning of multi-layer perceptron neural networks is performed by considering Gaussian probability distributions of the weights which can give the best generalisation [16-17]. In particular, the weights $w$ in network $X$ are adjusted to their most probable values given the training data $D$. Specifically, the posterior distribution of the weights can be computed using Bayes’ rule as follows

$$p(w | D, X) = \frac{p(D | w, X)p(w | X)}{p(D | X)} \quad (1)$$

where $p(D | w, X)$ is the likelihood function, which contains information about the weights from observations and the prior distribution $p(w | X)$ contains information about the weights from background knowledge. The denominator, $p(D | X)$, is known as the evidence for network $X$.

Regularisation can be used to prevent any weights becoming excessively large, which can lead to poor generalisation. For a multi-layer perceptron neural network classifier with $G$ groups of weights and biases, a weight decay penalty term proportional to the sum of squares of the weights and biases is added to the data error function $E_D$ to obtain the cost function

$$S = E_D + \sum_{g=1}^{G} \xi_g E_{W_g}, \quad E_{W_g} = \frac{1}{2} \|w_g\|^2 \quad (g = 1, ..., G) \quad (2)$$

where $S$ is called the cost function, $\xi_g$ is a non-negative scalar, sometimes known as a hyperparameter, ensuring the distribution of weights and biases in group $g$ and $w_g$ is the vector of weights and biases in group $g$. 
In network training, the hyperparameters are initialised to be arbitrary small values. The cost function is then minimised using an advanced optimisation technique. When the cost function has reached a local minimum, the hyperparameter $\xi_g$ \( g = 1, \ldots, G \) must be re-estimated. This task requires computing the Hessian matrix of the cost function:

$$A = H + \sum_{g=1}^{G} \xi_g I_g$$  \hspace{1cm} (3)

where $H$ is the Hessian matrix of $E_D$ and $I_g$ is the identity matrix, which selects weights in the $g$th group. The number of ‘well-determined’ weights $\gamma_g$ in group $g$ is calculated based on the old value of $\xi_g$ as follows \[15\]

$$\gamma_g = W_g - \xi_g tr(A^{-1}I_g), \quad \xi_g = \frac{\gamma_g}{2E_{W_g}} \quad (g = 1, \ldots, G) \hspace{1cm} (4)$$

The hyperparameters need to be re-estimated several times until the cost function value ceases to change significantly between consecutive re-estimation periods. After the network training is completed, the values of parameters $\gamma_g$ and $\xi_g$ are then used to compute the log evidence of network $X_i$ having $M$ hidden nodes as follows \[18-19\]

$$\ln Ev(X_i) = -S + \sum_{g=1}^{G} \frac{W_g}{2} \ln \xi_g - \frac{1}{2} \ln |H| + \ln M! + M \ln 2$$

$$+ \sum_{g=1}^{G} \frac{1}{2} \left( \frac{d\pi}{\gamma_g} \right) - G \ln(\ln \Omega) \quad (5)$$

where $W_g$ is the number of weights and biases in group $g$, and $\Omega$ is set to be $10^3$ \[19\]. However, $\Omega$ is a minor factor because it is the same for all models and therefore does not effect to the relative comparison of log evidence of different network architectures. The above Equation is used to compare different networks having different numbers of hidden nodes. The best network will be selected with the highest log evidence.

C. Study

Sixteen children with T1DM volunteered for the 10-hour overnight hypoglycemia study at the Princess Margaret Hospital for Children in Perth, Australia. Each patient was monitored overnight for the natural occurrence of nocturnal hypoglycemia. Data were collected with approval from Women’s and Children’s Health Service, Department of Health, Government of Western Australia, and with informed consent.

HypoMon was used to measure the relevant physiological responses. The four skin-surface bio-sensor electrodes are multiplexed and shared to measure both skin impedance and ECG signals. The responses from 16 T1DM children exhibit significant changes during the hypoglycemia phase against the non-hypoglycemia phase. Normalization was used to reduce patient-to-patient variability and to enable group comparison by dividing the patient’s heart rate, corrected QT interval and skin impedance by his/her corresponding values at time zero. The study shows that associated with hypoglycemic episodes in 16 T1DM children, using normalized values, their heart rates increase (1.082±0.298 vs. 1.033±0.242, P<0.06) and their corrected QT intervals increase significantly (1.060±0.084 vs. 1.031±0.086, P<0.001). However, in this clinical study (natural occurrence), the reduction of skin impedances of the patients were not strong (1.111±1.460 vs. 1.108±1.277, P<0.984). It should noted that in our previous 4-hour glucose clamp study \[8-9\], skin impedances reduced significantly during hypoglycemic episodes.

The detection of hypoglycemic episodes (BG≤60 mg/dl) using these variables is based on an optimal Bayesian neural network algorithm developed from the obtained clinical data. This neural network has a multilayer feed-forward neural network structure with one hidden node layer and one output node layer. In effect, it estimates the presence of hypoglycemia at sampling period $k$ based...
on the basis of the data at sampling period k and the
previous period at sampling period k-1. In general, the
sampling period is 5 minutes and approximately 30 data
points are used for each patient.

The overall data set consisted of a training set and a test
set, each with 8 cases randomly selected. For these, the
whole data set which included both hypoglycemia data part
and non-hypoglycemia data part were used. For optimal
robustness of the evaluation, we applied the evidence
framework for Bayesian inference to the training set and
found the feed forward neural network architecture with 10
hidden nodes yielded the highest evidence as shown in Fig.
3. The final feed-forward multi-layer neural network had
heart rate, corrected QT interval and skin impedance as
inputs, 10 hidden nodes and 1 output node (estimated blood
glucose level). From the optimal neural network which was
derived from the training set with the highest log evidence,
the sensitivity (true positive) value for detection of
hypoglycemia in the test set is 89.2%.

IV. CONCLUSION

The above result indicates that hypoglycemic episodes in
T1DM children can be detected non-invasively and
continuously effectively from the real-time physiological
responses measured by HypoMon. It is noted that the
relevant physiological parameters (QTC interval, heart rate
and skin impedance) are less correlated to the actual blood
glucose levels when the patients experienced hypoglycemic
episodes through natural occurrence against the situation
when clamp studies were performed. In this study, the
sensitivity obtained by the hypoglycemia detection neural
network is still low and its overall accuracy could be
improved. A more advanced neural network algorithm will
be developed to improve its overall accuracy further.
