This study compared membrane fouling in a sponge-submerged membrane bioreactor (SSMBR) and a conventional membrane bioreactor (CMBR) based on sludge properties when treating synthetic domestic wastewater. In the CMBR, soluble microbial products (SMP) in activated sludge were a major contributor for initial membrane fouling and presented higher concentration in membrane cake layer. Afterwards, membrane fouling was mainly governed by bound extracellular polymeric substances (EPS) in activated sludge, containing lower proteins but significantly higher polysaccharides. Sponge addition could prevent cake formation on membrane surface and pore blocking inside membrane, thereby alleviating membrane fouling. The SSMBR exhibited not only less growth of the biomass and filamentous bacteria, but also lower cake layer and pore blocking resistance due to lower bound EPS concentrations in activated sludge. Less

1 membrane fouling in SSMBR were also attributed to larger particle size, higher zeta
2
3 potential and relative hydrophobicity of sludge flocs.

11 12 13 14 15 **1. Introduction**

16
17 In the past decades, membrane bioreactor (MBR) has emerged as a considerably
18 alternative to the conventional activated sludge treatment system for water reclamation
19 and reuse. This technology has some superior merits, such as high effluent quality,
20 small footprint, complete liquid-solid separation, high biomass content, absolute control
21 of sludge retention time (SRT) and hydraulic retention time (HRT), and low sludge
22 production (Guo et al., 2009). However, membrane fouling, especially biofouling, is the
23 most obstacle in wide application of the MBR technology. Generally, biofouling is
24 referred to as undesirable accumulation of microorganisms at a phase transition
25 interface, which may occur by deposition, growth and metabolism of bacteria cells or
26 flocs on the membranes (Guo et al., 2012). As one of the most serious operational
27 problems in membrane applications, biofouling causes severe flux decline, reduces
28 membrane efficiency, increases membrane replacement and operational and
29 maintenance costs.

47
48
49
50
51

52 Various strategies have been employed to reduce membrane fouling in the MBRs.
53
54 Ngo and Guo (2009) found that an aerated submerged MBR (SMBR) system with
55 addition of a very low-dose green bioflocculant (GBF) could achieve near zero
56
57
58
59
60
61
62
63
64
65

1 membrane fouling after 70 days of operation as well as less backwash frequency. A
2
3 chemical cleaning-in-place (CIP) was investigated by Wei et al. (2011) in a long-term
4
5 operation of pilot-scale submerged MBR for municipal wastewater treatment. They
6
7 reported that the chemical CIP, in both transmembrane pressure (TMP) controlling
8
9 mode and time controlling mode, effectively removed the fouling in terms of membrane
10
11 pore blockage and gel layer caused by colloids and soluble organic substances. Wu and
12
13 He (2012) suggested that the low irreversible fouling was found in the cyclic aeration
14
15 mode, which could be ascribed to the floc destruction and re-flocculation processes.
16
17 During the short high aeration period, the preservation of the strong strength bonds
18
19 within activated sludge flocs caused less release of soluble and colloidal material in the
20
21 supernatant. The weak strength bonds damaged in the high aeration period could be
22
23 recovered in the re-flocculation process in the low aeration period.
24
25
26
27
28
29
30
31

32
33 In addition, using biomass carriers (e.g. plastic media, powdered activated carbon
34
35 (PAC), sponge) in MBR is an effective and promising method to control membrane
36
37 fouling. Jin et al. (2013) suggested that biomass flocs were less easily broken up with
38
39 addition of relatively light and large-sized suspended carriers (AnoxKaldnes, K1
40
41 carriers) in ceramic SMBR. Moreover, both extracellular polymer substances (EPS) and
42
43 soluble microbial products (SMP) were lower in the SMBR with carriers than those in
44
45 the SMBR without carriers. Ng et al. (2013) indicated that higher concentration of fresh
46
47 PAC in the SMBR could provide better simultaneous adsorption, decomposition, and
48
49 biodegradation effects for the reduction of fouling components in the supernatant of the
50
51 mixed liquor such as EPS, fine colloids and planktonic cells. As an idea attached growth
52
53 media, sponge has also exhibited excellent performance during biological treatment due
54
55
56
57
58
59
60
61
62
63
64
65

1 to its advantages of high internal porosity and specific surface area, high stability to
2
3 hydrolyses, light weight and low cost (Ngo et al., 2006). When employing in MBRs, it
4
5 can act as a mobile carrier for active biomass, reduce cake layer formation on the
6
7 membrane surface and retain microorganisms by incorporating both their attached
8
9 growth and suspended growth (Ngo et al., 2008). Guo et al. (2008) investigated the
10
11 effects of sponge addition on sustainable flux and membrane fouling. They found that
12
13 compared to SMBR alone, the suspended sponge cubes in the sponge-submerged
14
15 membrane bioreactor (SSMBR) with sponge volume fraction of 10% could significantly
16
17 reduce the membrane fouling as well as improve sustainable flux by 2 times. Nguyen et
18
19 al. (2012) also confirmed that SSMBR had lower TMP development than that of
20
21 conventional SMBR during primary effluent treatment. Meanwhile, SSMBR could
22
23 maintain good microbial activity and constant sludge volume index value.
24
25
26
27
28
29
30
31
32

33 Overall, previous studies have highlighted the advantages of sponge addition in
34
35 MBRs for improving treatment performance as well as membrane fouling reduction in
36
37 terms of sustainable flux or permeate flux. However, the effects of sponge on sludge
38
39 characteristics and membrane fouling have yet to be investigated in MBR systems.
40
41 Therefore, a comparison study was conducted to evaluate the performance of a SSMBR
42
43 and a conventional MBR (CMBR) based on sludge characteristics, such as zeta
44
45 potential, apparent viscosity, relative hydrophobicity (RH), EPS and SMP. The cake
46
47 layer formation on membrane surface was also analysed.

59
60
61
62
63
64
65

1 The experiments were conducted using a synthetic wastewater to avoid any
2 fluctuation in the feed concentration and provide a continuous source of biodegradable
3 organic pollutants such as glucose, ammonium sulfate and potassium dihydrogen
4 orthophosphate. It was used to simulate domestic wastewater just after primary
5 treatment. The synthetic wastewater has dissolved organic carbon (DOC) of 100–130
6 mg/L, chemical oxygen demand (COD) of 330–360 mg/L, ammonium nitrogen (NH₄-N)
7 of 12–15 mg/L and orthophosphate (PO₄-P) of 3.3–3.5 mg/L. NaHCO₃ or H₂SO₄ was
8 used to adjust pH to 7.
9

22 2.2. Experimental setup and operating conditions

25 A SSMBR and a CMBR with the same effective working volume were operated in
26 parallel to compare the performance and membrane fouling behavior. For each MBR, a
27 polyvinylidene fluoride (PVDF) hollow fiber module with a pore size of 0.2 μm and
28 surface area of 0.1 m² was used. Both MBRs were filled with sludge from a local
29 Wastewater Treatment Plant and acclimatized to synthetic wastewater. They were
30 started with identical seeding activated sludge with similar initial sludge concentration
31 (7.03 g/L for SSMBR, 6.98 g/L for CMBR). No sludge was withdrawn from both
32 MBRs. The reticulated porous polyester-polyurethane sponge (PUS) was used in
33 SSMBR system. The PUS has density of 28–45 kg/m³ and cell count of 45 cells/in (45
34 cells per 25.4 mm). The dimensions of the sponge cubes are 10 mm, 10 mm, and 10 mm
35 in length, width and thickness, respectively. The sponge volume fraction was 10% in
36 the SSMBR in this study, which was determined according to previous study of Guo et
37 al. (2008). Before running the experiments, the sponge cubes were acclimatized to
38 synthetic wastewater for 25 days. Synthetic wastewater was pumped into the reactor

1 using a feeding pump to control the feed rate while the effluent flow rate was controlled
2
3 by a suction pump. A pressure gauge was used to measure the TMP and a soaker hose
4
5 air diffuser was used to maintain air flow rate at 9 L/min. The filtration flux of both
6
7 MBRs was kept constant at 10 L/m²·h by adopting a suction cycle of 59-min on and 1-
8
9 min off (relaxation). For chemical cleaning of the membrane, the membrane was soaked
10
11 in chemical solutions using the three following steps: 6 h in 0.5% citric acid, 6 h in 0.4%
12
13 sodium hydroxide, 6 h in 0.8% sodium hypochlorite.
14

20 2.3. Analysis methods

21
22
23 DOC of the influent and effluent was measured using the Analytikjena Multi N/C
24
25 2000. The analysis of COD was according to Standard Methods (APHA, AWWA, WEF,
26
27 1998). NH₄-N and PO₄-P were measured by photometric method called Spectroquant[®]
28
29 Cell Test (NOVA 60, Merck).
30
31
32
33
34

35 Fouling resistance was measured through various fluxes with distilled water at the
36
37 end of the experiment. The resistance-in-series model was applied to evaluate
38
39 membrane filtration characteristics by using Darcy's law. The model was expressed as
40
41 follows (Choo and Lee, 1996):
42
43

$$44 J = \Delta P / \mu R_T \quad (1)$$

$$45 R_T = R_M + R_C + R_P \quad (2)$$

46
47
48 Where J is the permeate flux; ΔP is the TMP; μ is the viscosity of the permeate; R_T is
49
50 total resistance; R_M is the intrinsic membrane resistance; R_C is the cake resistance; and
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65
 R_P is the pore blocking resistance.

1 At the end of the experiment, the membrane was taken out from the bioreactor.
2
3 Cake layer on membrane surface was collected and then dissolved in 30 mL of distilled
4
5 water. The extraction procedures and analysis methods of EPS and SMP of cake layer
6
7 were in the same manner as described below. The EPS extraction protocol was modified
8
9 from Frølund et al. (1996). 30 mL of mixed liquor were taken from the MBRs and then
10
11 centrifuged at 3,000 rpm for 30 minutes. After that, the supernatant were centrifuged at
12
13 3,000 rpm for 30 minutes and filtered through 0.45 μm of Whatman 934-AH glass fiber
14
15 filter to obtain SMP. The pellets remaining in the centrifuge tube were suspended in
16
17 phosphorus buffer solution up to 30 mL, and then mixed with cation exchange resin for
18
19 2 h at 900 rpm. Extracted EPS were harvested by filtering the resin and solids mixture
20
21 through 1.2 μm Whatman 934-AH glass fiber filter. In this study, the extracted samples
22
23 were analysed for proteins (EPS_P and SMP_P) and polysaccharides (EPS_C and SMP_C)
24
25 concentrations using modified Lowry method (Sigma, Australia) and Anthrone-sulfuric
26
27 acid method, respectively.
28
29
30
31
32
33
34
35
36

37 The apparent viscosity and the zeta potential of mixed liquor were measured by
38
39 Brookfield Viscometer M/OO-151-E0808 and Zetasizer Nano ZS (Malvern Instruments,
40
41 UK), respectively. The relative hydrophobicity (RH) is the tendency of adherence of
42
43 sludge flocs to hydrocarbon (n-hexane in this study) and was measured following the
44
45 method by Ji et al. (2010). The equation $\text{RH} (\%) = (1 - \text{MLSS}_e / \text{MLSS}_i) \times 100\%$ was used
46
47 to calculate RH, where MLSS_e is the MLSS concentration in the aqueous phase after
48
49 emulsification and MLSS_i is the initial MLSS concentration of the sample. The
50
51 difference between MLSS_i and MLSS_e is hydrocarbon phase and the concentration of
52
53 sludge flocs adhering to n-hexane, indicating the hydrophobicity of sludge flocs. The
54

7
8
9

10 **3. Results and discussion**

11 *3.1. The performance of SSMBR and CMBR*

12
13 Table 1 summarizes the removal efficiency of DOC, COD, PO₄-P, NH₄-N and total
14
15 nitrogen (TN) in SSMBR and CMBR during the operation period. As shown in Table 1,
16
17 more than 90% of organic removal was obtained in both SSMBR and CMBR. SSMBR
18
19 showed higher performance for removing NH₄-N (> 70%) and PO₄-P (> 60%), while
20
21 around 60% of NH₄-N and 30% of PO₄-P were removed in the CMBR. Higher NH₄-N
22
23 removal in the SSMBR could be attributed to the enhanced population of ammonium
24
25 oxidation bacteria on the acclimatized sponge during acclimatization period (Nguyen et
26
27 al., 2012). As sponge could provide the anoxic condition around the surface of the
28
29 sponge and the anaerobic condition inside the sponge, the SSMBR achieved a higher
30
31 removal efficiency of PO₄-P (Guo et al., 2008).
32
33
34
35
36
37
38
39

40 **Table 1.**

41
42
43
44
45 Fig. 1 depicts the time course of TMP increase in both SSMBR and CMBR. Both
46
47 MBRs demonstrated significant difference in TMP profiles. TMP in the SSMBR was
48
49 maintained at 2.0 kPa up to 90 days. In the CMBR, TMP gradually increased from 5.0
50
51 kPa to 7.0 kPa until day 6, followed by a rapid TMP rise. After 35 days, the TMP
52
53 reached 31.0 kPa, suggesting chemical cleaning should be conducted for the membrane.
54
55
56
57
58
59
60
61
62
63
64
65

1 These results indicated that sponge addition could significantly mitigate membrane
2
3 fouling, which is further discussed in details in Section 3.5.
4

5
6 **Fig. 1.**
7
8
9

10 3.2. *Mixed liquor suspended solids (MLSS) concentration and apparent viscosity*

11
12 During the experimental period, sludge concentration kept increasing in both MBRs
13 due to no sludge withdrawal. MLSS concentrations were 11.50 ± 4.52 g/L and $9.41 \pm$
14 2.38 g/L in the CMBR and SSMBR after 35 and 90 days of operation, respectively. The
15 lower MLSS concentration in the SSMBR might be attributed to the fact that sponge
16 addition could balance the microorganism growth in suspended activated sludge as well
17 as on and inside the porous sponge cubes (Ngo et al., 2006). It was found that there is
18 an exponential relationship between MLSS concentration and sludge viscosity (Reid et
19 al., 2008). In this study, sludge viscosity was higher (3.30 ± 0.50 mPa·s) in the CMBR
20 than that (2.60 ± 0.40 mPa·s) in the SSMBR, demonstrating that higher sludge viscosity
21 was attributed to higher MLSS concentration. In addition, it has been reported that the
22 sludge flocs with excess filamentous bacteria showed high viscosity due to presence of
23 high EPS concentration (Meng et al., 2006a). Overgrowth of filamentous bacteria was
24 found in the CMBR on day 14, whereas there were less filamentous bacteria in the
25 SSMBR until 83 days, which revealed that higher sludge viscosity in the CMBR was
26 also due to abundance of filamentous bacteria. Similar observations were also recorded
27 by Meng et al. (2007) who suggested that sludge viscosity was influenced by MLSS
28 concentration, EPS and filamentous bacteria.

50
51
52
53
54
55
56

57 3.3. *Zeta potential, relative hydrophobicity (RH) and particle size distribution*

1 It has been demonstrated that the flocculation ability of sludge flocs is affected by
2
3 their hydrophobicity and surface charge, which positively influences the hydrophobic
4
5 interaction and electrostatic repulsion, respectively (Liao et al., 2001; Mikkelsen and
6
7 Keiding, 2002). In this study, activated sludge in the SSMBR had higher zeta potential
8
9 (- 6.85 ± 3.65 mV) and higher RH ($81.00 \pm 7.80\%$) than those in the CMBR (zeta
10
11 potential of -10.50 ± 4.50 mV, RH of $63.13 \pm 13.60\%$). The results indicated that there
12
13 might be a positive relationship between surface charge (zeta potential) and
14
15 hydrophobicity of activated sludge. Additionally, Meng et al. (2006a) reported that
16
17 excess filamentous bacteria could prevent the agglomeration of floc particles by
18
19 producing a bridge lattice due to the generation of abundant filaments from the flocs
20
21 into the bulk solution. Results of particle size distribution in this study showed that
22
23 larger sludge flocs (20–50 μm) were found in the SSMBR than those in the CMBR
24
25 (10–40 μm). This suggested that activated sludge had better flocculation ability in the
26
27 SSMBR, which might be due to higher RH and zeta potential of sludge flocs as well as
28
29 the presence of less filamentous bacteria.
30
31
32
33
34
35
36

37 38 39 40 41 *3.4. Bound EPS and SMP in activated sludge*

42 Normally, polysaccharides and proteins are considered as the major fractions of
43
44 EPS and SMP that contribute to fouling (Guo et al., 2012). Tables 2 and 3 exhibit
45
46 composition of mixed liquor's SMP and bound EPS in the SSMBR and CMBR. The
47
48 CMBR demonstrated higher SMP concentrations (around 2-3 times) within 7-day run.
49
50 The protein concentrations (SMP_p) were similar for both MBRs, while significantly
51
52 higher polysaccharide concentrations (SMP_c) were observed in the CMBR, suggesting
53
54 higher fouling propensity of the CMBR. Although activated sludge of both MBRs had
55
56
57
58
59
60
61
62
63
64
65

1 similar bound EPS concentrations, slightly higher protein concentrations (EPS_P) but
2
3 significantly lower polysaccharide concentrations (EPS_C) were obtained in the CMBR.
4
5 After 7 days of operation, the SMP concentrations (including SMP_P and SMP_C) of both
6
7 MBRs presented minor difference. On the other hand, bound EPS concentrations
8
9 (12.3–24.6 mg/L) in the CMBR were higher than those in the SSMBR (12.2–17.3
10
11 mg/L), with lower protein concentrations (EPS_P) but significantly higher polysaccharide
12
13 concentrations (EPS_C). In this study, increase of sludge concentration under infinite
14
15 SRT condition induced the decrease in food to microorganism (F/M) ratio ($0.1-0.2\text{ d}^{-1}$).
16
17 As a consequence, both MBRs were fed with limited available substrate, which could
18
19 cause more cell lysis and cell hydrolysis, thereby releasing EPS and SMP in activated
20
21 sludge (Yigit et al., 2008). Moreover, the excess growth of filamentous bacteria could
22
23 produce more SMP, resulting in severe fouling (Pan et al., 2010). Therefore, the CMBR
24
25 exhibited more serious fouling compared with the SSMBR. In the SSMBR, it was
26
27 obvious that sponge addition could reduce SMP_C concentrations during the first 7-day
28
29 run and EPS_C afterwards by the means of adsorption onto sponge as well as
30
31 biodegradation by attached biomass of the sponge.
32
33

34
35 It has been reported that large quantity of EPS in activated sludge increased floc
36
37 strength by polymer entanglement, thereby increasing the extent of sludge flocs
38
39 agglomeration (Mikkelsen and Keiding, 2002). However, in this study, lower EPS
40
41 concentration but larger particles were observed in the SSMBR, pointing out that the
42
43 flocculation ability of sludge flocs may not only depend on EPS concentration. Lee et al.
44
45 (2003) found that the ratio of proteins to polysaccharides (PN/PS ratio) in EPS was
46
47 important in controlling the hydrophobicity and surface charge of sludge flocs. Table 3
48
49
50
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 shows that a significantly higher PN/PS ratio in bound EPS was found in the SSMBR
2
3 after 7 days operation. Higher RH of activated sludge in the SSMBR proved that higher
4
5 EPS_P concentration increased the hydrophobicity of sludge flocs by providing amino
6
7 acids with more hydrophobic side groups, while lower EPS_C concentration contributed
8
9 to less hydrophilic nature of sludge. Moreover, the amino groups in EPS_P containing
10
11 positive charges neutralized some of negatively charged activated sludge, thereby
12
13 inducing higher zeta potential of sludge flocs in the SSMBR (Lee et al., 2003; Liao et
14
15 al., 2001). Thus, PN/PS ratio in bound EPS could positively influence hydrophobicity
16
17 and zeta potential of activated sludge, thereby having an impact on the agglomeration
18
19 ability of the flocs.
20

32 *3.5. Membrane fouling behaviour*

34 Results of fouling resistance showed that the CMBR had a higher total resistance
35
36 (R_T) ($5.47 \times 10^{12} \text{ m}^{-1}$) than that of the SSMBR ($2.56 \times 10^{12} \text{ m}^{-1}$). The clean membrane
37
38 resistance (R_M) were the same ($1.71 \times 10^{12} \text{ m}^{-1}$) for both MBRs. Higher cake layer
39
40 resistance (R_C) was found for the CMBR than that for the SSMBR, corresponding to
41
42 $3.04 \times 10^{12} \text{ m}^{-1}$ and $0.85 \times 10^{12} \text{ m}^{-1}$, respectively. Moreover, pore blocking resistance
43
44 (R_P) for the CMBR was notably higher. R_P of the CMBR accounted for about 20% of
45
46 R_T , whereas there was no R_P in the SSMBR. These results suggested that cake layer
47
48 formation was one of the main factors contributing to membrane fouling. Furthermore,
49
50 sponge could alleviate membrane fouling not only by preventing pore blocking but also
51
52 by reducing cake layer formation. Some researchers (Jamal Khan et al., 2012; Yang et
53
54
55
56
57
58
59
60
61
62
63
64
65

1 al., 2006) have reported the similar findings that R_C was major fraction of R_T and
2
3 sponge addition could reduce R_C .
4

5
6
7
8 As discussed in Section 3.2, activated sludge in both MBRs possessed different
9
10 properties, which were correlated with membrane fouling potential as well as fouling
11
12 resistance. Higher MLSS concentration could lead to formation of a sticky cake layer on
13
14 membrane surface due to higher sludge viscosity (Itonaga et al., 2004). Additionally,
15
16 the sludge flocs with abundance of filamentous bacteria would more easily deposit on
17
18 membrane surface due to its high viscosity, causing the formation of a non-porous cake
19
20 layer (Meng et al., 2006a). Therefore, it could be noted that higher MLSS concentration
21
22 and overgrowth of filamentous bacteria contributed to formation of sticky and non-
23
24 porous cake layer, giving rise to higher R_C in the CMBR. Being the major fraction of
25
26 the total fouling resistance, the cake layer was analysed with respect to EPS and SMP
27
28 (including polysaccharides and proteins). Fig. 2 shows the composition of EPS and
29
30 SMP in the cake layer on membrane surface for both SSMBR and CMBR. Bound EPS
31
32 concentrations were similar for the SSMBR (15.0 mg/(L·g cake layer)) and the CMBR
33
34 (13.9 mg/(L·g cake layer)). However, higher concentrations of SMP_C and SMP_P (14.4
35
36 and 15.5 mg/(L·g cake layer), respectively) were obtained for the CMBR, while SMP_C
37
38 and SMP_P of the cake layer were comparatively lower for the SSMBR (9.8 and 7.1
39
40 mg/(L·g cake layer), respectively). These results elucidated that higher R_C in the CMBR
41
42 was mainly caused by SMP (including SMP_C and SMP_P) on membrane surface. At high
43
44 TMP, more SMP_C and SMP_P could be adsorbed and/or attached onto membrane surface
45
46 due to the high drag force provided by permeate pump. On contrary, sponge addition
47
48 effectively reduced SMP_C and SMP_P in cake layer on membrane surface. Apart from
49
50
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 adsorption of SMP_C and SMP_P on the sponge and biodegradation by attached
2
3 microorganisms, reduction of cake layer could be also attributed to physical clearance
4
5 mechanism of sponge, such as frictional force exerted by circulating media on
6
7 submerged membrane, solute back-transport effect from the membrane surface to the
8
9 bulk solution due to turbulence of suspended carriers, and membrane shaking by the
10
11 impact of suspended carriers against them (Lee et al., 2006; Yang et al., 2006).
12
13
14

15 **Fig. 2.**

16
17
18
19
20 Since particles could lead to severe membrane fouling by pore blocking and cake
21
22 formation on the membrane (Lim and Bai, 2003), the CMBR contained smaller sludge
23
24 flocs and induced higher TMP increment rate (Fig. 1), which illustrated that the
25
26 presence of smaller sludge flocs contributed to higher R_C and R_P in the CMBR. As
27
28 larger particles could not easily deposit on membrane surface due to higher shear
29
30 induced diffusion and inertial lift force, SSMBR demonstrated significantly lower
31
32 membrane fouling propensity (Pan et al., 2010).
33
34
35
36
37
38
39

40 In addition, as above-mentioned in Section 3.4, SMP in activated sludge appeared
41
42 as a major contribution to initial membrane fouling. However, in later stage, membrane
43
44 fouling development was mainly governed by bound EPS in activated sludge. It has
45
46 been showed that SMP could increase fouling tendency due to the combined effects of
47
48 pore clogging and adsorption on membrane walls and within membrane pores (Shen et
49
50 al., 2012). Thus, higher SMP content of the CMBR cake layer led to higher R_P , which
51
52 was well consistent with the results by Jamal Khan et al. (2012). Besides, higher
53
54 concentration of bound EPS in activated sludge could also increase both R_C and R_P in
55
56
57
58
59
60
61
62
63
64
65

1 the CMBR. Ng et al. (2006) observed a thick fouling layer on the membrane consisting
2
3 of microbial cells covered with EPS, which blocked membrane pores. Similar results
4
5 were also found by Meng et al. (2006b) that the total amount of EPS had a significant
6
7 positive correlation with the fouling resistance caused by pore blocking and cake
8
9 formation.
10
11

12
13
14
15 Previous studies have reported that PN/PS ratio in EPS or SMP had a significant
16
17 impact on filtration resistance as well as fouling propensity (Lee et al., 2003; Tian et al.,
18
19 2011; Yao et al., 2011). In this study, as both SMP and EPS (especially SMP_C and EPS_C)
20
21 were responsible for membrane fouling in the CMBR, a new fouling indicator
22
23 $((SMP_C/SMP_P)/(EPS_C/EPS_P))$ has been developed. There was a strong correlation
24
25 between fouling rate and fouling indicator $((SMP_C/SMP_P)/(EPS_C/EPS_P) = 9.6727$
26
27 $(dTMP/dt) - 8.3431, R^2 = 0.9783$). Generally, polysaccharides can penetrate into the
28
29 cake layer and membrane pores, as well as lead to irreversible fouling due to their
30
31 partially hydrophilic nature comparing to proteins (Kimura et al., 2004; Meng et al.,
32
33 2009; Guo et al., 2012). Hence, SMP_C can be a greater contribution to irreversible
34
35 fouling than EPS_C . When activated sludge has higher SMP_C concentration but lower
36
37 EPS_C concentration, the value of $(SMP_C/SMP_P)/(EPS_C/EPS_P)$ will be higher, indicating
38
39 more severe membrane fouling and higher fouling rate $(\Delta TMP/\Delta t)$, and vice versa.

Highlights

- Less SMP and bound EPS in activated sludge in the SSMBR induced lower R_C and R_p .
- Lower biomass growth and sludge viscosity contributed to lower R_C in the SSMBR.
- Larger sludge flocs, higher zeta potential and RH led to lower R_T in the SSMBR.
- Sponge could prevent pore blocking and cake layer formation.
- Sponge addition could reduce SMP_C and EPS_C through adsorption and biodegradation.
