University of Technology Sydney, NSW 2007, Australia

Abstract—**Improvements in characteristics of magnetic materials and switching devices have provided the feasibility of replacing the electrical buses with high frequency magnetic links in micro-grids. This effectively reduces the number of voltage conversion stages, and the size and cost of the renewable energy system. It also isolates the converter ports which increases the system safety and facilitates bidirectional power flow and energy management. To design the magnetic link optimally, an accurate evaluation of copper loss of the windings considering both current waveforms and parasitic effects is required. This paper studies the accurate copper loss analysis of a three-winding high-frequency magnetic link for residential micro-grid applications. Due to the non-sinusoidal nature of the voltage and currents, the loss analysis is carried out on a harmonic basis taking into account variations of phase shift, duty ratio and amplitude of wave-forms. The high frequency skin and proximity effects are taken into account. The maximum and minimum copper loss operating points of the converter and their dependency on the phase shift and duty ratio of the waveforms are studied and simulation results are presented.**

Index Terms—**Copper loss, harmonics, high-frequency magnetic link, multi-winding transformer, phase-shift, proximity, skin effects**

I. INTRODUCTION

HIGH-FREQUENCY magnetic links have attracted a lot of research interest due to their application in the integration of renewable energy resources into the grid. The magnetic link is a multi-winding high frequency transformer which provides bidirectional paths for magnetic fluxes and power flows between different ports. As a feasible replacement for conventional electrical buses, it can be used to integrate renewable energies in smart grids. It can reduce effectively the number of conversion stages and improve the conversion efficiency using lossless switching devices and modern soft magnetic materials. Other advantages are galvanic isolation and bidirectional power flow capability between the converter ports [1]-[6]. Fig.1 illustrates two renewable energy systems with and without the magnetic link. The dashed lines show that the power flow path from PV array to the battery has been reduced effectively with the use of the magnetic link. Therefore employing the magnetic link can reduce the number of voltage conversion units, increase the system efficiency and reduce the system's size and cost. To optimally design the magnetic link, the winding loss should be accurately evaluated considering non-sinusoidal effects of the voltage and current waveforms [7].

The high frequency time-varying harmonics of non-sinusoidal currents produce the well-known skin and proximity effects which cause a non-uniform distribution of the current in the wire area [7],[8]. Due to the dependency of these effects to operating frequency, a frequency-dependent resistance model is used to analyze the copper loss [9]-[13].To reduce the copper loss, Litz wires are recommended for high frequency applications [9]-[14]. The loss evaluation of Litz wire windings is mainly based on either numerical [9], [10] or analytical [11]–[19] field analysis. The numerical methods provide more accurate results although they are relatively complicated and computationally expensive. On the contrary, the analytical methods are easy for design purposes and present good accuracy where Litz wire strand radius remains below the skin depth [7], [22]. The analytical methods in turn can be divided into three groups [7]. A majority of works are based on Dowell's work in 1966 on loss analysis of foil and round conductors using the Maxwell's equations in Cartesian coordinates [11]. They have extended the Dowell's method for foil conductors to the Litz wire windings of the same cross-section area and have applied a porosity factor to the resultant equation to increase the accuracy [12],[13]. The second approach known as Ferreira method is based on exact field solution of stand-alone round conductor using Bessel functions [14]. The analysis was later extended to a complete winding [15], [16] and an expression was introduced using modified Bessel functions to improve the accuracy of the method in high frequency applications [17]. In the third group, conduction loss is calculated using complex conductor permeability [18]. The method provides a good accuracy although it is complicated to determine the real and imaginary parts of the winding permeability [7]. The first two methods are widely used in the literature and their accuracy is compared [16], [19]. Both methods provide good accuracy especially where strand diameter is much lower than the skin depth [7], [13], [16]. A detailed study on copper loss analysis of buck and fly-back dc-dc converters under variable duty ratio based on the first analytical method has been presented recently [20],[21] although none of these studies deal with the multiple winding transformer and phase shifted waveforms. In [8] the copper loss of a dual active bridge (DAB) bidirectional converter is studied considering the effects of phase shift of voltages applied to the transformer.

In this paper, research in [8] is extended to the case of three-winding magnetic link while both amplitude and phase shifts are variable. The maximum and minimum loss conditions are defined for two common micro-grid operation modes known as DAB and triple active bridge (TAB).

Fig. 2. Schematic of the proposed residential micro-grid

II. APPLICATION OF MAGNETIC LINK IN RESIDENTIAL MICRO-GRID

The proposed micro-grid topology including three-winding magnetic link is illustrated in Fig.2. As can be seen in the figure, the proposed topology includes four ports. Port one, two and three are linked together through the magnetic link and form a TAB phase shift converter. They are used to convert the dc voltage of fuel cell, PV and inverter bus to a high frequency ac voltage fed to the windings of the magnetic link. Port four links the battery to the fuel cell bus to store the surplus energy of the system and release it when is required. It also operates in standby mode to balance the voltage of the fuel cell bus in transients due to slow dynamic response of fuel cell. The system is connected to the residential load and grid via a single phase bidirectional inverter and is designed to supply a 5 kW residential load. Two digital signal processors (TMS320F28335) are used to control the dc-dc converters and inverter at the device level. The system level control and energy management, considering both long term and short term load and energy forecasts is performed in a PC system. The regional distribution network control center communicates with energy management unit (EMU) via internet (through either cable or wireless).

To control the power flow from PV and fuel cell ports to the inverter, the waveforms of the voltages of port two and three are shifted for leading phase angles of φ_{21} and φ_{31} compared to port one to send power to the inverter. In the PV port, switching devices of H-bridge dc-ac converter are shared with an interleaved current-fed boost converter. The interleaved boost converter is used to maintain MPPT through duty ratio control while dc-bus voltage regulation is carried out using phase shift angle φ_{31}. The voltage on the PV port changes reversely with duty ratio to keep the equal volt-seconds on all three windings of the magnetic link and guarantees the zero voltage switching (ZVS) operation of TAB converter ports. The proposed micro-grid can operate in various operation modes based on the power flow directions and active ports.
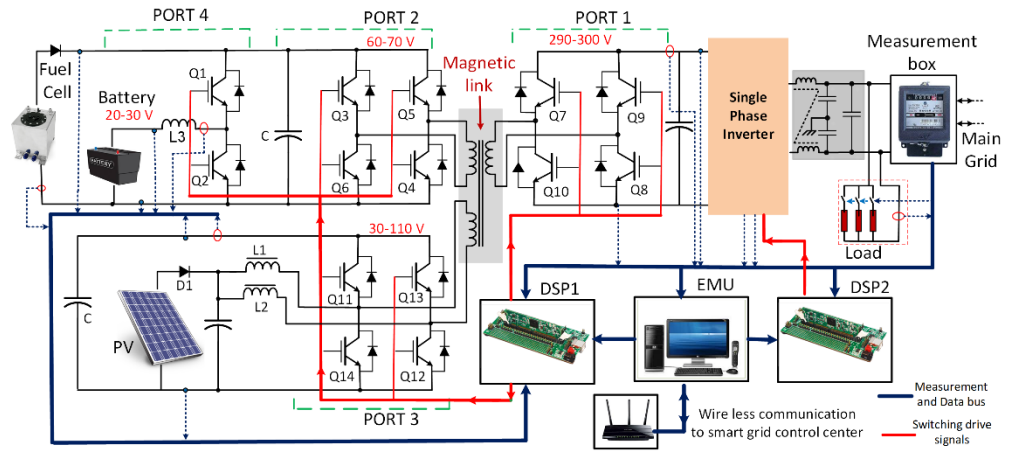

III. COPPER LOSS ANALYSIS METHOD

Due to the linear behavior of copper, conduction loss analysis is carried out based on the harmonic contents of the currents in the windings of the magnetic link [7], [8], [20], [21]. Therefore, the total copper loss can be defined by integration of resultant loss of each harmonic component of the current as following

$$P_{Cu} = \sum_{n=1}^{h} P_{Cu,n} \tag{1}$$

where $P_{Cu,n}$ is the resultant copper loss of nth harmonic and h is the number of harmonics that are effective in loss analysis.

The skin and proximity effects on the windings resistance can be considered separately for copper loss analysis of each harmonic due to their orthogonality principle [23]. Their effect is modelled as a frequency-dependent resistance for each harmonic in the case of non-sinusoidal currents. Therefore, the resultant loss of the nth harmonic, $P_{Cu,n}$, is calculated by

$$P_{Cu,n} = \left(\frac{I_n}{\sqrt{2}}\right)^2 R_{ac,n} \tag{2}$$

where $R_{ac,n}$ is the ac resistance of the Litz-wire winding for nth harmonic and I_n the peak value of nth harmonic of the non-sinusoidal current in the winding. To calculate the copper loss using (1) and (2) for the proposed magnetic link, the analytical methods of calculating equivalent ac resistance $R_{ac,n}$, and amplitude of each harmonic I_n, are discussed in the following sections.

IV. HARMONIC BASED ANALYSIS OF THE CURRENTS IN THE MAGNETIC LINK

The leakage inductances of the windings of the magnetic link are the main elements of the power transfer between the ports in the proposed TAB converter. A T-model configuration of the three-winding magnetic link can be obtained by referring leakage inductances of windings two and three to winding one as reference (magnetizing inductance is neglected as it has no effect on power transfer). The resultant model then can be transformed to the equivalent Δ-model to obtain the simplified TAB converter model as presented in Fig.3 [3],[6]. On the other hand, the dc-bus and H-bridge converters are replaced with an equivalent square

wave ac source. The leading phase shift angles, φ_{21} and φ_{31}, are assumed between voltages of ports two and three to port one (selected as reference port) as presented in Fig.4. This is because power transfers from fuel cell and PV ports to the inverter port. A zero-voltage angle Ω, is introduced in the PV port ac voltage v_3, to maintain the MPPT. Therefore, the dc voltage on PV port V_3, should be varied accordingly to maintain the ZVS operation.

$$V_3 = \frac{1}{1-(\Omega/\pi)}V_{3-min} \tag{3}$$

where V_3 is the actual value and V_{3-min} is the minimum value of voltage on PV port. The duty ratio D, can be defined from

$$D = (1-\Omega/\pi) \tag{4}$$

In this paper, the duty ratio of fuel cell and inverter ports is kept constant ($D=1$, $\Omega=0$) due to the constant voltage of their buses.

The harmonic based analysis of non-sinusoidal currents has been widely used for copper loss analysis of transformers [8], [20], [21]. To calculate the copper loss in the proposed magnetic link, currents in the windings are analyzed using the equivalent Δ-model. Therefore, fundamental-harmonic phasor diagram of the currents and voltages in the equivalent Δ-model, presented in Fig.5 is used as a reference in the following analysis.

The high frequency square wave voltages illustrated in Fig.4, are represented based on their Fourier series as

$$v_1(t) = \sum_{n=1}^{\infty} V_{1,n}\sin(n\omega t)$$

$$v_2(t) = \sum_{n=1}^{\infty} V_{2,n}\sin(n(\omega t + \varphi_{21})) \tag{5}$$

$$v_3(t) = \sum_{n=1}^{\infty} V_{3,n}\sin(n(\omega t + \varphi_{31}))$$

where $V_{k,n}$ is the amplitude of the nth harmonic of the voltage across winding k. For port one and port two due to their constant amplitude, we have

$$V_{k,n} = \frac{2V_k(1-\cos(n\pi))}{n\pi}, \qquad k=1,2 \tag{6}$$

For port three, due to the variable amplitude and duty ratio, it can be calculated by

$$V_{3,n} = \frac{2V_{3-min}\cos(n\Omega/2)(1-\cos(n\pi))}{n(\pi-\Omega)} \tag{7}$$

As can be seen in the equivalent model, $i_1=i_{13}-i_{21}$, $i_2=i_{21}-i_{32}$ and $i_3=i_{32}-i_{13}$. Therefore, to analyze the current in the winding one i_1, the currents i_{21} and i_{13} should be calculated by using voltage across inductances L_{21} and L_{13}. The voltage v_{21} can be calculated using (5) by

$$v_{21}(t) = v_2(t) - v_1(t) = \sum_{n=1}^{\infty} V_{21,n}\cos(n\omega t + \alpha_n) \tag{8}$$

where $V_{21,n}$ is the amplitude of nth harmonic of $v_{21,n}$ and is defined from

$$V_{21,n} = \sqrt{V_{1,n}^2 + V_{2,n}^2 - 2V_{1,n}V_{2,n}\cos(n\varphi_{21})} \tag{9}$$

and the phase angle of nth harmonic α_n, is calculated using

$$\alpha_n = \tan^{-1}\frac{V_{2,n}\sin(n\varphi_{21})}{V_{2,n}\cos(n\varphi_{21})-V_{1,n}} \tag{10}$$

Fig. 3. The Δ-model equivalent circuit of three winding magnetic link.

Fig.4. Voltage and current wave forms related to current i_1 in winding one.

Fig.5. Fundamental phasor diagram of the TAB converter

The current i_{21} can then be calculated taking into account $\pi/2$ as inductive phase shift angle by

$$i_{21} = \sum_{n=1}^{\infty} I_{21,n}\sin(n\omega t + \alpha_n - \frac{\pi}{2}) \tag{11}$$

where $I_{21,n}$ is the amplitude of the nth harmonic of $i_{21,n}$ and can be calculated by

$$I_{21,n} = \frac{V_{21,n}}{(2\pi nfL_{21})} \tag{12}$$

The current i_{13} in the winding L_{13} is defined similar to i_{21} from (13) considering φ_{31} as the phase shift angle between v_3 to v_1, $I_{13,n}$ as the amplitude and $(\beta_n-\pi/2)$ as the phase angle of nth harmonic.

$$i_{31} = \sum_{n=1}^{\infty} I_{31,n}\sin(n\omega t + \beta_n - \frac{\pi}{2}) \tag{13}$$

Finally, the nth harmonic of the current in the source v_1 and in the winding one of the magnetic link $i_{1,n}$ (refer to Fig.3) can be calculated using (11) and (13) by

$$i_{1,n}(t) = i_{13,n} - i_{21,n} = I_{1,n}\sin(n\omega t + \psi_{1,n}) \tag{14}$$

where $I_{1,n}$ and $\psi_{1,n}$ are the amplitude and the phase angle of nth harmonic of i_1 respectively and can be determined by

$$I_{1,n} = \sqrt{I_{13,n}^2 + I_{21,n}^2 - 2I_{13,n}I_{21,n}\cos(n(\beta_n-\alpha_n))} \tag{15}$$

$$\psi_{1,n} = \tan^{-1}\left(\frac{I_{13,n}\sin(n\beta_n)-I_{21,n}\sin(n\alpha_n)}{I_{13,n}\cos(n\beta_n)-I_{21,n}\cos(n\alpha_n)}\right) \tag{16}$$

The amplitude of each harmonic of the current in winding two, $I_{2,n}$ and the phase angle $\psi_{2,n}$ and in winding three, $I_{3,n}$ and $\psi_{3,n}$ can be calculated in a similar way. It can be seen from (5) and (7) that v_1, v_2 and v_3 and consequently the resultant current in the windings only contain the odd harmonics. Once the harmonic content of the current in the windings ($i_{1,n}$, $i_{2,n}$ and $i_{3,n}$) is determined, the ac resistance factor of each winding $R_{ac,n}$, related to each harmonic term should be defined for loss analysis. The next section provides the details of calculating ac resistance.

V. CALCULATION OF AC RESISTANCE

The skin and proximity effects are considerable in medium and high-frequency applications. To reduce these effects the stranded, twisted insulated conductors known as Litz wires should be used. Considering these high frequency effects, the ac resistance of a Litz wire winding is a function of frequency while the dc resistance is relatively constant and for each winding can be calculated by

$$R_{dc} = \frac{4Nl_s\rho_{Cu}}{n_s\pi d_{str}^2} \qquad (17)$$

where N is the turns number of winding, l_s the average length of one turn, ρ_{cu} the resistivity of copper, d_{str} the strand diameter and n_s the number of strands. The skin and proximity effect losses related to each harmonic of the current can be modeled through a frequency-dependent resistance, $R_{ac,n}$ [7]-[17]. The ratio of $R_{ac,n}$ to R_{dc} known as the ac resistance factor $F_{r,n}$, can be defined as

$$F_{r,n} = \frac{R_{ac,n}}{R_{dc}} \qquad (18)$$

In the case of using Litz wires the skin and proximity effects appear in both strand and bundle levels [13]. The bundle level proximity effect can be reduced efficiently by twisting; however, bundle level skin effect needs more complex constructions [13], [22]. On the other hand the strand level proximity effect is more considerable compared with skin effects especially in the case of increasing number of layers [22]. The skin and proximity effects analysis in Litz wires are carried out based on two best-known analytical methods, the Dowell method and Ferreira method. In the first method, the round conductors are replaced with square conductors of the same area and then an equivalent foil conductor the same as the one that Dowell analyzed is found. The one dimensional field analysis is applied to the foil to find the losses [11]-[13]. The second approach is based on the field analysis of a single round conductor using well-known Bessel functions and some of its applications are proposed by Ferreira [14]-[17]. Both methods provide similar results and accuracy for small penetration ratios [8] although it has been shown that the second method provides more accurate results in high frequency applications [17]. In this paper the first method is used for our special case due to its simplicity, relatively low switching frequency (10 kHz) and penetration ratio. In this method (proposed in 1966), the skin and proximity effect losses of an isolated solid round conductor were evaluated using an exact solution of the internal and external magnetic fields [14] and further developed by Ferreira in 1990 [22], [23]. The closed form expression considering orthogonality of skin and proximity effects can be written as

$$F_{r,n} = \frac{\gamma_n}{2}\left[\tau_{1,n} - 2\pi\frac{4(m^2-1)}{3}\tau_{2,n}\right] \qquad (19)$$

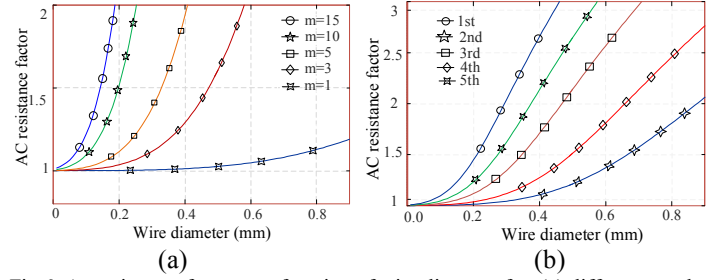

Fig.6. Ac resistance factor as a function of wire diameter for: (a) different number of winding layers, and (b) various harmonics of the current in windings of the magnetic link.

with

$$\tau_{1,n} = \frac{ber(\gamma_n)bei'(\gamma_n) - bei(\gamma_n)ber'(\gamma_n)}{ber'(\gamma_n)^2 + bei'(\gamma_n)^2} \qquad (20)$$

$$\tau_{2,n} = \frac{ber_2(\gamma_n)ber'(\gamma_n) + bei_2(\gamma_n)bei'(\gamma_n)}{ber'(\gamma_n)^2 + bei'(\gamma_n)^2} \qquad (21)$$

where ber and bei are the real and imaginary parts of the first kind Bessel function and γ_n is the round conductor penetration ratio of the nth harmonic and is defined as

$$\gamma_n = \frac{d}{\delta_n\sqrt{2}} \qquad (22)$$

VI. COPPER LOSS EVALUATION OF THE MAGNETIC LINK

This section reviews the loss calculation of the magnetic link considering all effective elements. As can be seen in (19)-(21), the harmonic frequency, strand diameter and number of winding layers have major effects on the ac resistance factor and consequently the copper loss. Fig.6 (a) illustrates the effect of increasing the number of winding layers on the ac resistance factor. As can be seen the ac resistance of the wire decreases by reducing number of windings layers and using strands of less diameter. Fig.6 (b) shows the ac resistance factor, $F_{r,n}$ for the five major harmonics of the converter currents. It can be seen that the ac resistance factor reduces for lower harmonic orders and strand diameters. Therefore, reducing operation frequency reduces not only the switching loss but also the winding losses in the converters.

A. Calculation of maximum copper loss

The maximum copper loss is important in the optimal design and thermal analysis of the magnetic link. According to the power flow equation of TAB converter, maximum power flow and *rms* current in the magnetic link take place when fuel cell and PV ports are transferring maximum power ($\varphi_{21}=\pi/2$, $\varphi_{31}=\pi/2$)[3]-[7]. On the other hand, when PV bus voltage V_3, is maximized and duty ratio D, is minimized, the amplitude of the fundamental harmonic of the current in winding three increases and raises the loss. Therefore, duty ratio is equal to its minimum value when copper loss in winding three is maximized (D=0.25 and Ω=3π/4 in this case). The power losses of all windings were analytically calculated for the specified operation point and are integrated to define the maximum copper loss of the magnetic link. Fig.7 illustrates the calculated value of ac resistance $R_{ac,n}$, amplitude of harmonic I_n, and the resultant copper loss $P_{cu,n}$ of each harmonic of the current in the windings.
Fig.7. Calculated value of ac resistance R_{ac}, copper loss and harmonic amplitudes of the three windings of the magnetic link for maximum conduction loss condition (a) winding one, (b) winding two, and (c) winding three

Fig.8. Conduction loss of the windings one and three for zero voltage angle, $\Omega=0$ to $3\pi/4$ and phase shift angle, $\varphi_{31}= 0$ to $\pi/2$.
Fig.9. Trends of the windings current in the magnetic link versus phase shift angle

Fig.10. Copper loss of the magnetic link for different values of φ_{21} and φ_{31}

As can be seen the copper loss is decreased with increasing the harmonic orders as the effect of reduction in harmonic amplitude overcomes the increasing ac resistance. The calculated value of copper losses of windings one, two and three using (1) are equal to 15 W, 37 W and 78 W respectively. Therefore, the maximum copper loss of the magnetic link in this operation mode is 130 W.

B. Loss analysis under phase shift angle and duty ratio variation

To study the effect of variation of phase shift angle φ_{31} and zero voltage angle Ω of the PV port on the copper loss, two common operation modes have been considered. In the first operation mode only the PV and inverter ports are active and the dc-dc converter operates in DAB mode. The phase shift angle, φ_{31} was changed from 0 to $\pi/2$ and the zero voltage angle Ω, from 0 to $3\pi/4$ (assuming that voltage of PV port varies from 30 V to 120 V). The copper loss of the magnetic link for the entire operation range was calculated according to the method discussed in section III and is presented in Fig.8. It can be seen that in general any increase in the phase shift angle and zero voltage angle increases the copper loss although the effect of phase shift angle is more considerable compared to that of zero voltage angle. Increasing zero voltage angle at higher phase shift angles raises the amplitude of fundamental component of the current in the PV port which results in more effect on the copper loss at higher phase shift angles. As expected the maximum loss takes place at $\varphi_{31}=\pi/2$ and $\Omega=3\pi/4$ which is about 60 W. In the second case the converter operated in the TAB mode and both fuel cell and PV ports were active and transferred power to the inverter port. The fuel cell port was operating with the constant phase shift angle

and duty ratio ($\varphi_{21}=\pi/2$, $\Omega=0$) due to the constant voltage of the bus. At the PV port, the bus voltage V_3, zero voltage angle Ω and the phase shift angle φ_{31} has been changed similar to the previous stage.

Fig.9 illustrates the overall trend of the currents in the equivalent Δ-model (i_{21}, i_{13} and i_{32}) and in the windings (i_1, i_2 and i_3) with the variation of phase shift angle, φ_{31}. As can be seen increasing φ_{31} raises i_{31} and the power transferred from PV to the inverter while i_{21} remains constant due to the constant value of φ_{21}. On the other hand, increasing φ_{31} reduces φ_{23} (as $\varphi_{23}=\varphi_{21}-\varphi_{31}$) and i_{32} and consequently the power transferred from fuel cell port to PV port. Referring to the Δ-model nodal equations ($i_1=i_{13}-i_{21}$, $i_2=i_{21}-i_{32}$ and $i_3=i_{32}-i_{13}$), one can see that when φ_{31} increases, i_1 and consequently copper loss in winding one increases while i_2 and copper loss in winding two decreases. In winding three, i_3 decreases for phase shift angles less than $\pi/4$ and then increases. This is because, for small phase values of φ_{31}, the power received from port two is more than the power transferred to port one. At $\varphi^*_{31}=\varphi_{21}/2=\pi/4$ the powers received from port two and transferred to port one are almost equal. Therefore the average power of the port and the current i_3 are minimized at this point and the copper loss of winding three and the total copper loss of the magnetic link are minimized at this point. As can be seen in Fig.10, the minimum loss point where $\varphi_{31}= \varphi^*_{31}$ depends on the φ_{21} and always $\varphi^*_{31} =\varphi_{21}/2$ where the received and transferred powers to the port three are equal. The resultant copper loss of all windings and the total loss according to the phase shift angle φ_{31}, and zero voltage angle Ω, variations are presented in Fig.11.
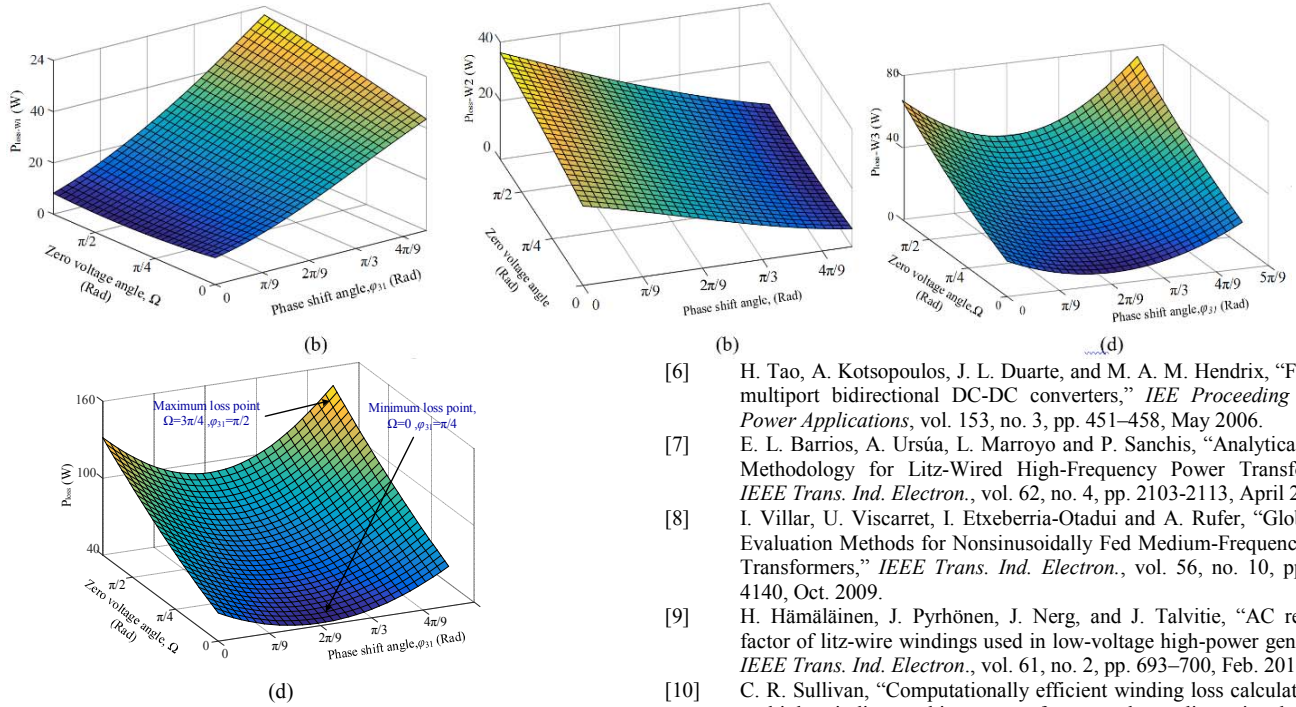

(b)

(b)

(d)

(d)

Fig.11. Conduction loss of the magnetic link for zero voltage angle, Ω=0 to $3\pi/4$ and phase shift angle, φ_{31}= 0 to $\pi/2$.(a). winding one, W1. (b)winding two,W2. (c) winding three, W3, and (d) total magnetic link.

As can be seen in Fig.11 (a)-(b), increasing phase shift angle φ_{31}, raises the loss in winding one and decreases the average power, current and loss of winding two. As presented in Fig.11(c)-(d), the copper loss of winding three and the total loss are minimized at $\varphi_{31}= \varphi^*=\pi/4$ due to the previous discussions.

VII. CONCLUSION

An accurate method of copper loss analysis based on the harmonic contents of the excitation waveforms for a multi-winding magnetic link is discussed in this paper. The phase shift angle, duty ratio and amplitude variation of the voltages of the ports on the copper loss have been taken into account. The high frequency skin and proximity effect losses are considered using the ac resistance factor of the Litz wire windings. The total copper loss of the magnetic link and the maximum and minimum copper loss operating points for two cases of DAB and TAB modes are calculated analytically.
