77 **Ongoing declines among the world's coral reefs^{1,2} require novel approaches to**
78 **sustain these ecosystems and the millions of people who depend on them³. A**
79 **presently untapped approach that draws on theory and practice in human health**
80 **and rural development^{4,5} is systematically identifying and learning from the**
81 **'outliers'- places where ecosystems are substantially better ('bright spots') or**
82 **worse ('dark spots') than expected, given the environmental conditions and**
83 **socioeconomic drivers they are exposed to. Here, we compile data from more**
84 **than 2,500 reefs worldwide and develop a Bayesian hierarchical model to**
85 **generate expectations of how standing stocks of reef fish biomass are related to**
86 **18 socioeconomic drivers and environmental conditions. We then identified 15**
87 **bright spots and 35 dark spots among our global survey of coral reefs, defined as**
88 **sites that had biomass levels more than two standard deviations from**
89 **expectations. Importantly, bright spots were not simply comprised of remote**
90 **areas with low fishing pressure- they include localities where human populations**
91 **and use of ecosystems resources is high, potentially providing novel insights into**
92 **how communities have successfully confronted strong drivers of change.**
93 **Alternatively, dark spots were not necessarily the sites with the lowest absolute**
94 **biomass and even included some remote, uninhabited locations often considered**
95 **near-pristine⁶. We surveyed local experts about social, institutional, and**
96 **environmental conditions at these sites to reveal that bright spots were**
97 **characterised by strong sociocultural institutions such as customary taboos and**
98 **marine tenure, high levels of local engagement in management, high dependence**
99 **on marine resources, and beneficial environmental conditions such as deep-**
100 **water refuges. Alternatively, dark spots were characterised by intensive capture**
101 **and storage technology and a recent history of environmental shocks. Our**

102 **results suggest that investments in strengthening fisheries governance,**
103 **particularly aspects such as participation and property rights, could facilitate**
104 **innovative conservation actions that help communities defy expectations of**
105 **global reef degradation.**

106

107 *Main text*

108 Despite substantial international conservation efforts, many of the world's ecosystems
109 continue to decline^{1,7}. Most conservation approaches aim to identify and protect
110 places of high ecological integrity under minimal threat⁸. Yet, with escalating social
111 and environmental drivers of change, conservation actions are also needed where
112 people and nature coexist, especially where human impacts are already severe⁹. Here,
113 we highlight an approach for implementing conservation in coupled human-natural
114 systems focused on identifying and learning from outliers - places that are performing
115 substantially better than expected, given the socioeconomic and environmental
116 conditions they are exposed to. By their very nature, outliers deviate from
117 expectations, and consequently can provide novel insights on confronting complex
118 problems where conventional solutions have failed. This type of positive deviance, or
119 'bright spot' analysis has been used in fields such as business, health, and human
120 development to uncover local actions and governance systems that work in the
121 context of widespread failure^{10,11}, and holds much promise in informing conservation.

122

123 To demonstrate this approach, we compiled data from 2,514 coral reefs in 46
124 countries, states, and territories (hereafter 'nation/states') and developed a Bayesian
125 hierarchical model to generate expected conditions of how standing reef fish biomass
126 (a key indicator of resource availability and ecosystem functions¹²) was related to 18
127 key environmental variables and socioeconomic drivers (Box 1; Extended Data
128 Tables 1,2; Methods). A key and significant finding from our global analysis is that
129 the size and accessibility of the nearest market, more so than local or national
130 population pressure, management, environmental conditions, or national
131 socioeconomic context, was the strongest driver of reef fish biomass globally (Box 1).

132

133 Next, we identified 15 ‘bright spots’ and 35 ‘dark spots’ among the world’s coral
134 reefs, defined as sites with biomass levels more than two standard deviations higher or
135 lower than expectations from our global model, respectively (Fig. 1; Methods;
136 Extended Data Table 3). Rather than simply identifying places in the best or worst
137 condition, our bright spots approach reveals the places that most strongly defy
138 expectations. Using them to inform the conservation discourse will certainly
139 challenge established ideas of where and how conservation efforts should be focused.
140 For example, remote places far from human impacts are conventionally considered
141 near-pristine areas of high conservation value⁶, yet most of the bright spots we
142 identified occur in fished, populated areas (Extended Data Table 3), some with
143 biomass values below the global average. Alternatively, some remote places such as
144 parts of the NW Hawaiian Islands underperform (i.e. were identified as dark spots).

145

146 Detailed analysis of why bright spots can evade the fate of similar areas facing
147 equivalent stresses will require a new research agenda gathering detailed site-level
148 information on social and institutional conditions, technological innovations, external
149 influences, and ecological processes¹³ that are simply not available in a global-scale
150 analysis. To catalyse this process, we surveyed local experts about these issues for the
151 15 bright spots, 35 dark spots, and 14 average sites with biomass values closest to
152 model expectations (Methods). Bright spots were characterised by substantial local
153 engagement in the management process, higher dependence on coastal resources, and
154 the presence of sociocultural governance institutions such as customary tenure or
155 taboos (Fig. 2, Methods). For example, in one bright spot, Karkar Island, Papua New
156 Guinea, resource use is restricted through an adaptive rotational harvest system based

157 on ecological feedbacks, marine tenure that allows for the exclusion of fishers from
158 outside the local village, and initiation rights that limit individuals' entry into certain
159 fisheries¹⁴. Bright spots were also generally proximate to deep water, which may help
160 provide a refuge from disturbance for corals and fish¹⁵ (Fig. 2, Extended Data Fig. 6).
161 Conversely, dark spots were distinguished by having fishing technologies allowing
162 for more intensive exploitation, such as fish freezers and potentially destructive
163 netting, as well as a recent history of environmental shocks (*e.g.* coral bleaching or
164 cyclone; Fig. 2). The latter is particularly worrisome in the context of climate change,
165 which is likely to lead to increased coral bleaching and more intense cyclones¹⁶.

166

167 Our global analyses highlight two novel opportunities to inform coral reef
168 governance. The first is to use bright spots as agents of change to expand the
169 conservation discourse from the current focus on protecting places under minimal
170 threat⁸, toward harnessing lessons from places that have successfully confronted high
171 pressures.

172 Our bright spots approach can be used to inform the types of investments and
173 governance structures that may help to create more sustainable pathways for impacted
174 coral reefs. Specifically, our initial investigation highlights how investments that
175 strengthen fisheries governance, particularly issues such as participation and property
176 rights, could help communities to innovate in ways that allow them to defy
177 expectations. Conversely, the more typical efforts to provide capture and storage
178 infrastructure, particularly where there are environmental shocks and local-scale
179 governance is weak, may lead to social-ecological traps¹⁷ that reinforce resource
180 degradation beyond expectations. Effectively harnessing the potential to learn from
181 both bright and dark spots will require scientists to increase research efforts in these

182 places, NGOs to catalyze lessons from other areas, donors to start investing in novel
183 solutions, and policy makers to ensure that governance structures foster flexible
184 learning and experimentation. Indeed, both bright and dark spots may have much to
185 offer in terms of how to creatively confront drivers of change, identify the paths to
186 avoid and those offering novel management solutions, and prioritizing conservation
187 actions. Critically, the bright spots we identified span the development spectrum from
188 low income (Solomon Islands and Papua New Guinea) to high (territories of the USA
189 and UK; Fig. 1), showing that lessons about effective reef management can emerge
190 from diverse places.

191

192 A second opportunity stems from a renewed focus on managing the socioeconomic
193 drivers that shape reef conditions. Many social drivers are amenable to governance
194 interventions, and our comprehensive analysis (Box 1) shows how an increased policy
195 focus on social drivers such as markets and development could result in
196 improvements to reef fish biomass. For example, given the important influence of
197 markets in our analysis, reef managers, donor organisations, conservation groups, and
198 coastal communities could improve sustainability by developing interventions that
199 dampen the negative influence of markets on reef systems. Markets not only affect
200 price and price variability for reef products¹⁸, creating incentives for overexploitation,
201 but also influence people's behavior¹⁹, including their willingness to cooperate in the
202 collective management of natural resources²⁰. A portfolio of market interventions,
203 including eco-labelling and sustainable harvesting certifications, fisheries
204 improvement projects, and value chain interventions have been developed within
205 large-scale industrial fisheries²¹⁻²³. There is considerable scope for adapting these
206 interventions to artisanal coral reef fisheries in both local and regional markets.

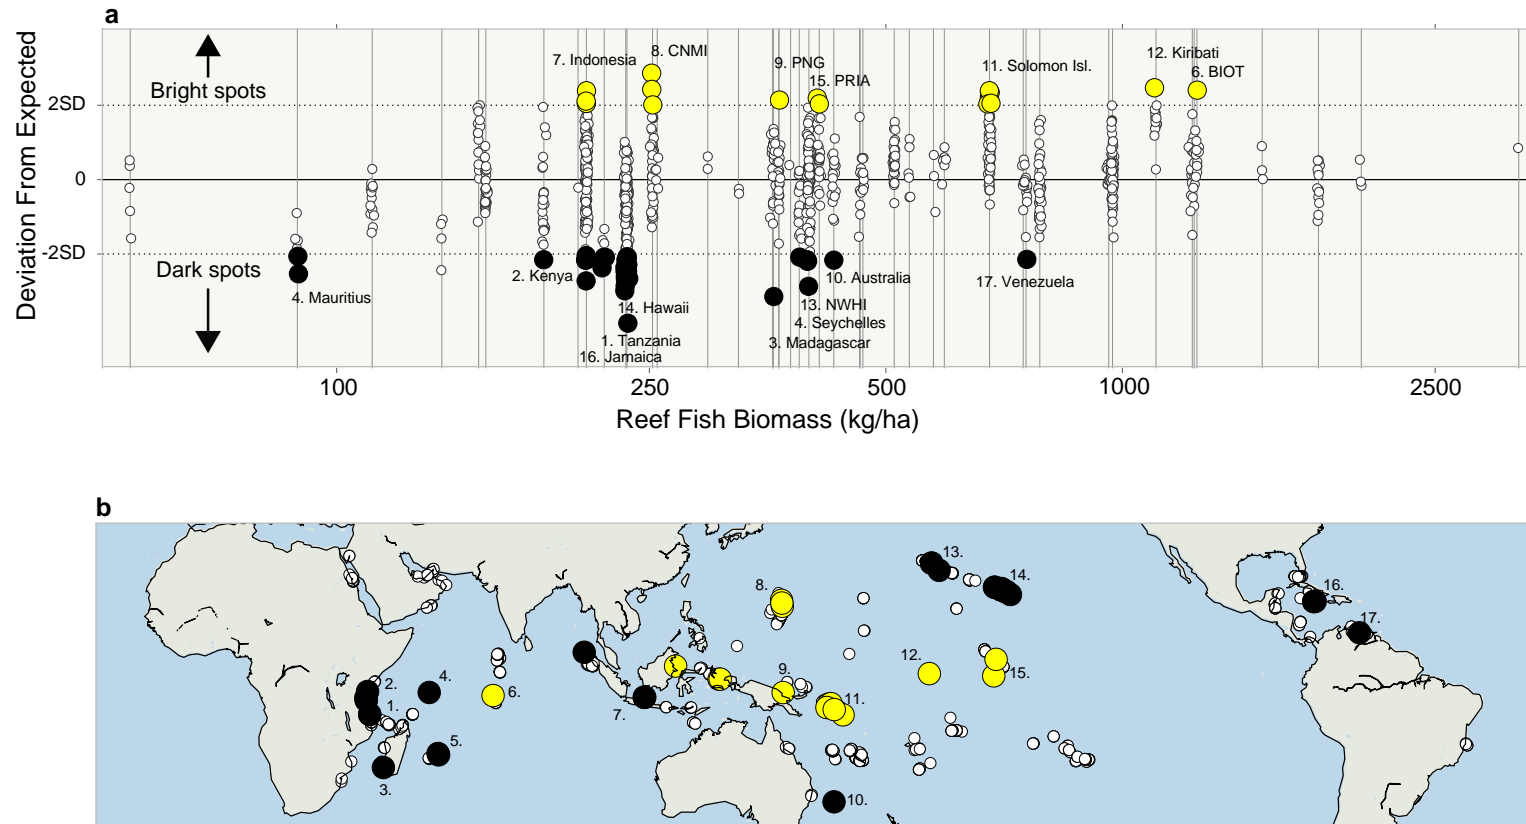

207 However, these interventions need to be coupled with mechanisms to ensure an
208 equitable distribution of benefits²⁴ as well as effective policy reforms, such as limited
209 entry or total allowable catch limits, supply chain traceability, and investments in
210 local management capacity to ensure that fisheries are exploited at sustainable levels
211 and livelihood benefits are secured.

212

213 The long-term viability of coral reefs will ultimately depend on international action to
214 reduce carbon emissions¹⁶. However, fisheries remain a pervasive source of reef
215 degradation, and local-level fisheries governance is crucial to sustaining ecological
216 processes that give reefs the best chance of coping with global environmental
217 change²⁵. Effectively doing so will require novel approaches to conservation that
218 embrace reefs as coupled human-natural systems and seek to confront, rather than
219 avoid, drivers of change. By emulating the lessons learned from bright spots and
220 dampening the drivers of reef exploitation, we can create a brighter future for the
221 world's coral reefs.

222

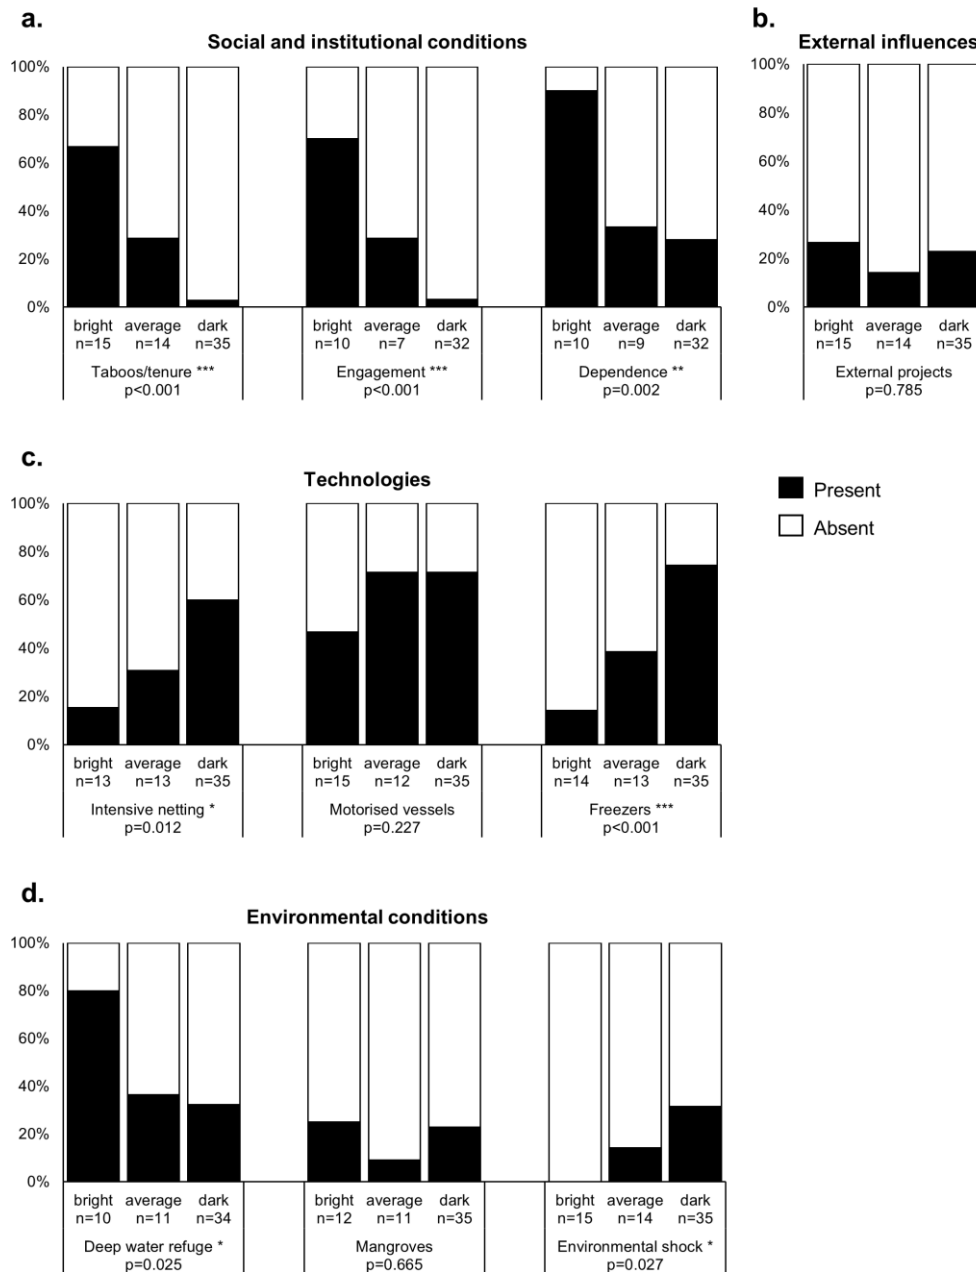

223 **Figures**

224

225 **Figure 1 | Bright and dark spots among the world's coral reefs.** (a) Each site's deviation from expected biomass (y-axis) along a gradient of
 226 nation/state mean biomass (x-axis). Sites with biomass values >2 standard deviations above or below expected values were considered bright and
 227 dark spots, respectively. The 15 bright and 35 dark spots are indicated with yellow and black dots respectively. Each grey vertical line represents

228 a nation/state in our analysis. Nation/states with bright or dark spots are labelled and numbered, corresponding to the numbers in panel b. There
229 can be multiple bright or dark spots in each nation/state, thus the 50 bright and dark spots are distributed among 17 nation/states. As a
230 conservative precaution, we did not consider a site bright or dark spot if there were fewer than 5 sites sampled in a nation/state (Methods);
231 consequently there is one site with biomass levels lower than 2 SD below expectations that is not labelled as a dark spot. BIOT= British Indian
232 Ocean Territory (Chagos); PNG= Papua New Guinea; CNMI= Commonwealth of the Northern Mariana Islands; NWHI= Northwest Hawaiian
233 Islands; PRIA= Pacific Remote Island Areas. (b) Map highlighting bright spots and dark spots with large circles, and other sites in small circles.
234 Bright spots are mostly concentrated on islands of the Pacific and Southeast Asia, while dark spots are spread among every major tropical ocean
235 basin.

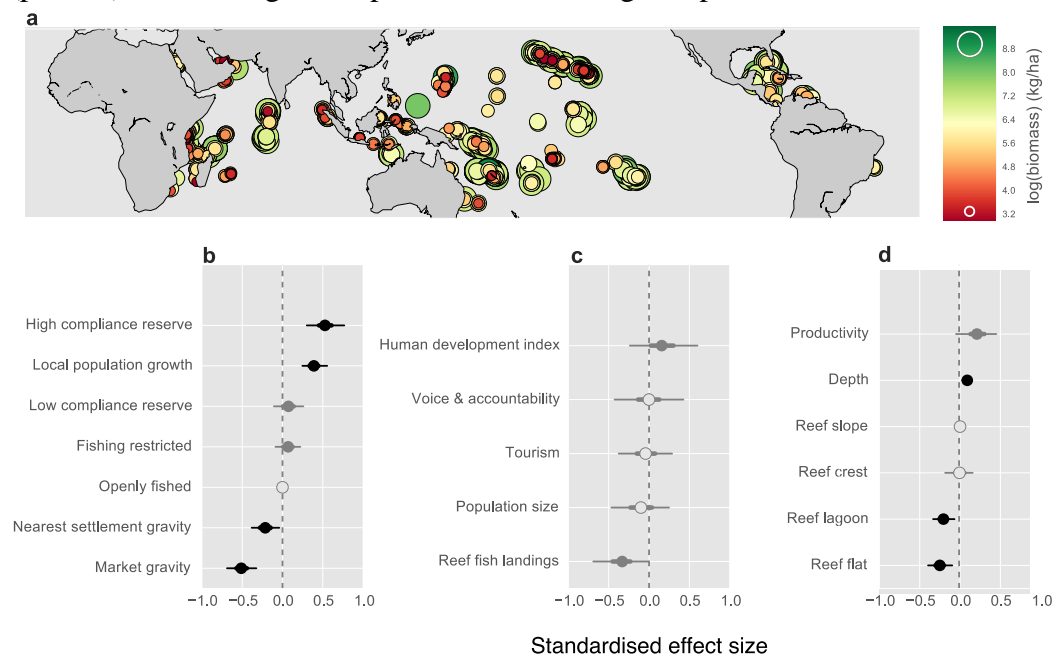

236
237
238
239
240

Figure 2 | Differences in social and environmental conditions between bright spots, dark spots, and ‘average’ sites. *=p<0.05, **=p<0.01, *=p<0.001. P values are determined using Fisher’s Exact test. Intensive netting includes beach seine nets, surround gill nets, and muro-ami.**

Box 1

Drawing on a broad body of theoretical and empirical research in the social sciences^{24,26,27} and ecology^{2,6,28} on coupled human-natural systems, we quantified how reef fish biomass (panel a) was related to distal social drivers such as markets, affluence, governance, and population (panels b,c), while controlling for well-known environmental conditions such as depth, habitat, and productivity (panel d) (Extended Data Table 1, Methods). In contrast to many global studies of reef systems that are focused on demonstrating the severity of human impacts⁶, our examination seeks to uncover potential policy levers by highlighting the relative role of specific social drivers. Critically, the strongest driver of reef fish biomass (*i.e.* the largest standardized effect size) was our metric of potential interactions with urban centres, called market gravity²⁹ (Extended Data Fig. 1, 2, 3; Methods). Specifically, we found that reef fish biomass decreased as the size and accessibility of markets increased (Extended Data Fig. 2b, and Extended Data Fig. 3). Somewhat counter-intuitively, fish biomass was higher in places with high local human population growth rates, likely reflecting human migration to areas of better environmental quality³⁰-a phenomenon that could result in increased degradation at these sites over time. We found a strong positive, but less certain relationship (*i.e.* a high standardized effect size, with >75% of the posterior distribution above zero) with the Human Development Index, meaning that reefs tended to be in better condition in wealthier nation/states (panel c). Our analysis also confirmed the role that marine reserves can play in sustaining biomass on coral reefs, but only when compliance is high (panel b), reinforcing the importance of fostering compliance for reserves to be successful.

Global patterns and drivers of reef fish biomass. (a) Reef fish biomass [in (log)kg/ha] among 918 study sites across 46 nations/states. For illustration purposes and to avoid the overlap of sites in a global map, we display sites as points that vary in size and colour proportional to amount of fish biomass, with small, red dots indicating low fish biomass and large, green dots indicating high biomass. b-d) Standardised effect size of local scale social drivers, nation/state scale social drivers, and environmental covariates, respectively. Parameter estimates are Bayesian posterior median values, 95% uncertainty intervals (UI; thin lines), and 50% UI (thick lines). Black dots indicate that the 95% UI does not overlap 0; Grey closed circles indicates that 75% of the posterior distribution lies to one side of 0; and grey open circles indicate that the 50% UI overlaps 0.

242 **Methods**

243

244 Scales of data

245 Our data were organized at three spatial scales: reef (n=2514), site (n=918), and
246 nation/state (n=46).

247 i) reef (the smallest scale, which had an average of 2.4 surveys/transects -
248 hereafter 'reef').

249 ii) site (a cluster of reefs). We clustered reefs together that were within 4km of
250 each other, and used the centroid of these clusters (hereafter 'sites') to
251 estimate site-level social and site-level environmental covariates (Extended
252 Data Table 1). To make these clusters, we first estimated the linear distance
253 between all reefs, then used a hierarchical analysis with the complete-
254 linkage clustering technique based on the maximum distance between reefs.
255 We set the cut-off at 4km to select mutually exclusive sites where reefs
256 cannot be more distant than 4km. The choice of 4km was informed by a 3-
257 year study of the spatial movement patterns of artisanal coral reef fishers,
258 corresponding to the highest density of fishing activities on reefs based on
259 GPS-derived effort density maps of artisanal coral reef fishing activities³¹.
260 This clustering analysis was carried out using the R functions 'hclust' and
261 'cutree', resulting in an average of 2.7 reefs/site.

262 iii) Nation/state (nation, state, or territory). A larger scale in our analysis was
263 'nation/state', which are jurisdictions that generally correspond to
264 individual nations (but could also include states, territories, overseas regions,
265 or extremely remote areas within a state such as the northwest Hawaiian

266 Islands; Extended Data Table 2), within which sites and reefs were nested
267 for analysis.

268

269 Estimating Biomass

270 Reef fish biomass can reflect a broad selection of reef fish functioning and benthic
271 conditions^{12,32-34}, and is a key metric of resource availability for reef fisheries. Reef
272 fish biomass estimates were based on instantaneous visual counts from 6,088 surveys
273 collected from 2,514 reefs. All surveys used standard belt-transects, distance
274 sampling, or point-counts, and were conducted between 2004 and 2013. Where data
275 from multiple years were available from a single reef, we included only data from the
276 year closest to 2010. Within each survey area, reef associated fishes were identified to
277 species level, abundance counted, and total length (TL) estimated, with the exception
278 of one data provider who measured biomass at the family level. To make estimates of
279 biomass from these transect-level data comparable among studies, we:

280 i) Retained families that were consistently studied and were above a
281 minimum size cut-off. Thus, we retained counts of >10cm diurnally-
282 active, non-cryptic reef fish that are resident on the reef (20 families, 774
283 species), excluding sharks and semi-pelagic species (Extended Data Table
284 4). We also excluded three groups of fishes that are strongly associated
285 with coral habitat conditions and are rarely targets for fisheries (Anthiinae,
286 Chaetodontidae, and Cirrhitidae). We calculated total biomass of fishes on
287 each reef using standard published species-level length-weight relationship
288 parameters or those available on FishBase³⁵. When length-weight
289 relationship parameters were not available for a species, we used the
290 parameters for a closely related species or genus.

- 291 ii) Directly accounted for depth and habitat as covariates in the model (see
292 “environmental conditions” section below);
- 293 iii) Accounted for any potential bias among data providers (capturing
294 information on both inter-observer differences, and census methods) by
295 including each data provider as a random effect in our model.

296

297 Biomass means, medians, and standard deviations were calculated at the reef-scale.

298 All reported log values are the natural log.

299

300 Social Drivers

301 *1. Local Population Growth:* We created a 100km buffer around each site and used
302 this to calculate human population within the buffer in 2000 and 2010 based on the
303 Socioeconomic Data and Application Centre (SEDAC) gridded population of the
304 world database³⁶. Population growth was the proportional difference between the
305 population in 2000 and 2010. We chose a 100km buffer as a reasonable range at
306 which many key human impacts from population (e.g., land-use and nutrients) might
307 affect reefs³⁷.

308

309 *2. Management:* For each site, we determined if it was: i) unfished- whether it fell
310 within the borders of a no-take marine reserve. We asked data providers to further
311 classify whether the reserve had high or low levels of compliance; ii) restricted -
312 whether there were active restrictions on gears (e.g. bans on the use of nets,
313 spearguns, or traps) or fishing effort (which could have included areas inside marine
314 parks that were not necessarily no take); or iii) fished - regularly fished without
315 effective restrictions. To determine these classifications, we used the expert opinion

316 of the data providers, and triangulated this with a global database of marine reserve
317 boundaries³⁸.

318

319 3. *Gravity*: We adapted the economic geography concept of *gravity*, also called
320 interactance³⁹, to examine potential interactions between reefs and: i) major urban
321 centres/markets (defined as provincial capital cities, major population centres,
322 landmark cities, national capitals, and ports); and ii) the nearest human settlements
323 (Extended Data Fig. 1). This application of the gravity concept infers that potential
324 interactions increase with population size, but decay exponentially with the effective
325 distance between two points. Thus, we gathered data on both population estimates and
326 a surrogate for distance: travel time.

327

328 *Population estimations*

329 We gathered population estimates for: 1) the nearest major markets (which
330 includes national capitals, provincial capitals, major population centres, ports,
331 and landmark cities) using the World Cities base map from ESRITM; and 2) the
332 nearest human settlement within a 500km radius using LandScanTM 2011
333 database. The different datasets were required because the latter is available in
334 raster format while the former is available as point data. We chose a 500km
335 radius from the nearest settlement as the maximum distance any non-market
336 fishing activities for fresh reef fish are likely to occur.

337

338 *Travel time calculation*

339 Travel time was computed using a cost-distance algorithm that computes the
340 least 'cost' (in minutes) of travelling between two locations on a regular raster

341 grid. In our case, the two locations were either: 1) the centroid of the site (i.e.
342 reef cluster) and the nearest settlement, or 2) the centroid of the site and the
343 major market. The cost (i.e. time) of travelling between the two locations was
344 determined by using a raster grid of land cover and road networks with the
345 cells containing values that represent the time required to travel across them⁴⁰
346 (Extended Data Table 5), we termed this raster grid a *friction-surface* (with the
347 time required to travel across different types of surfaces analogous to different
348 levels of friction). To develop the friction-surface, we used global datasets of
349 road networks, land cover, and shorelines:

- 350 - Road network data was extracted from the Vector Map Level 0
351 (VMap0) from the National Imagery and Mapping Agency's (NIMA)
352 Digital Chart of the World (DCW®). We converted vector data from
353 VMap0 to 1km resolution raster.
- 354 - Land cover data were extracted from the Global Land Cover 2000⁴¹.
- 355 -To define the shorelines, we used the GSHHS (Global Self-consistent,
356 Hierarchical, High-resolution Shoreline) database version 2.2.2.

357

358 These three friction components (road networks, land cover, and water bodies)
359 were combined into a single friction surface with a Behrmann map projection.
360 We calculated our cost-distance models in R⁴² using the *accCost* function of
361 the '*gdistance*' package. The function uses Dijkstra's algorithm to calculate
362 least-cost distance between two cells on the grid and the associated distance
363 taking into account obstacles and the local friction of the landscape⁴³. Travel
364 time estimates over a particular surface could be affected by the infrastructure
365 (e.g. road quality) and types of technology used (e.g. types of boats). These

366 types of data were not available at a global scale but could be important
367 modifications in more localised studies.

368

369 *Gravity computation*

370 i) To compute the gravity to the nearest market, we calculated the population of
371 the nearest major market and divided that by the squared travel time between
372 the market and the site. Although other exponents can be used⁴⁴, we used the
373 squared distance (or in our case, travel time), which is relatively common in
374 geography and economics. This decay function could be influenced by local
375 considerations, such as infrastructure quality (e.g. roads), the types of transport
376 technology (i.e. vessels being used), and fuel prices, which were not available
377 in a comparable format for this global analysis, but could be important
378 considerations in more localised adaptations of this study.

379 ii) To determine the gravity of the nearest settlement, we located the nearest
380 populated pixel within 500kms, determined the population of that pixel, and
381 divided that by the squared travel time between that cell and the reef site.

382 As is standard practice in many agricultural economics studies⁴⁵, an assumption in
383 our study is that the nearest major capital or landmark city represents a market.

384 Ideally we would have used a global database of all local and regional markets for
385 coral reef fish, but this type of database is not available at a global scale. As a
386 sensitivity analysis to help justify our assumption that capital and landmark cities
387 were a reasonable proxy for reef fish markets, we tested a series of candidate
388 models that predicted biomass based on: 1) cumulative gravity of all cities within
389 500km; 2) gravity of the nearest city; 3) travel time to the nearest city; 4)
390 population of the nearest city; 5) gravity to the nearest human population above 40

391 people/km² (assumed to be a small peri-urban area and potential local market); 6)
392 the travel time between the reef and a small peri-urban area; 7) the population size
393 of the small peri-urban population; 8) gravity to the nearest human population
394 above 75 people/km² (assumed to be a large peri-urban area and potential market);
395 9) the travel time between the reef and this large peri-urban population; 10) the
396 population size of this large peri-urban population; and 11) the total population
397 size within a 500km radius. Model selection revealed that the best two models
398 were gravity of the nearest city and gravity of all cities within 500km (with a 3
399 AIC value difference between them; Extended Data Table 6). Importantly, when
400 looking at the individual components of gravity models, the travel time
401 components all had a much lower AIC value than the population components,
402 which is broadly consistent with previous systematic review studies⁴⁶. Similarly,
403 travel time to the nearest city had a lower AIC score than any aspect of either the
404 peri-urban or urban measures. This suggests our use of capital and landmark cities
405 is likely to better capture exploitation drivers from markets rather than simple
406 population pressures. This may be because market dynamics are difficult to
407 capture by population threshold estimates; for example some small provincial
408 capitals where fish markets are located have very low population densities, while
409 some larger population centres may not have a market. Downscaled regional or
410 local analyses could attempt to use more detailed knowledge about fish markets,
411 but we used the best proxy available at a global scale.

412

413 *4. Human Development Index (HDI):* HDI is a summary measure of human
414 development encompassing: a long and healthy life, being knowledgeable, and having

415 a decent standard of living. In cases where HDI values were not available specific to
416 the State (e.g. Florida and Hawaii), we used the national (e.g. USA) HDI value.

417

418 *5. Population Size:* For each Nation/state, we determined the size of the human
419 population. Data were derived mainly from census reports, the CIA fact book, and
420 Wikipedia.

421

422 *6. Tourism:* We examined tourist arrivals relative to the nation/state population size
423 (above). Tourism arrivals were gathered primarily from the World Tourism
424 Organization's Compendium of Tourism Statistics.

425

426 *7. National Reef Fish Landings:* Catch data were obtained from the Sea Around Us
427 Project (SAUP) catch database (www.searoundus.org), except for Florida, which
428 was not reported separately in the database. We identified 200 reef fish species and
429 taxon groups in the SAUP catch database⁴⁷. Note that reef-associated pelagics such as
430 scombrids and carangids normally form part of reef fish catches. However, we chose
431 not to include these species because they are also targeted and caught in large
432 amounts by large-scale, non-reef operations.

433

434 *8. Voice and Accountability:* This metric, from the World Bank survey on
435 governance, reflects the perceptions of the extent to which a country's citizens are
436 able to participate in selecting their government, as well as freedom of expression,
437 freedom of association, and a free media. In cases where governance values were not
438 available specific to the Nation/state (e.g. Florida and Hawaii), we used national (e.g.
439 USA) values.

440

441 Environmental Drivers

442 *1. Depth:* The depth of reef surveys were grouped into the following categories: <4m,
443 4-10m, >10m to account for broad differences in reef fish community structure
444 attributable to a number of inter-linked depth-related factors. Categories were
445 necessary to standardise methods used by data providers and were determined by pre-
446 existing categories used by several data providers.

447

448 *2. Habitat:* We included the following habitat categories: i) Slope: The reef slope
449 habitat is typically on the ocean side of a reef, where the reef slopes down into deeper
450 water; ii) Crest: The reef crest habitat is the section that joins a reef slope to the reef
451 flat. The zone is typified by high wave energy (i.e. where the waves break). It is also
452 typified by a change in the angle of the reef from an inclined slope to a horizontal reef
453 flat; iii) Flat: The reef flat habitat is typically horizontal and extends back from the
454 reef crest for 10's to 100's of metres; iv) Lagoon / back reef: Lagoonal reef habitats
455 are where the continuous reef flat breaks up into more patchy reef environments
456 sheltered from wave energy. These habitats can be behind barrier / fringing reefs or
457 within atolls. Back reef habitats are similar broken habitats where the wave energy
458 does not typically reach the reefs and thus forms a less continuous 'lagoon style' reef
459 habitat. Due to minimal representation among our sample, we excluded other less
460 prevalent habitat types, such as channels and banks. To verify the sites' habitat
461 information, we used the Millennium Coral Reef Mapping Project (MCRMP)
462 hierarchical data⁴⁸, Google Earth, and site depth information.

463

464 3. *Productivity*: We examined ocean productivity for each of our sites in mg C / m² /
465 day (<http://www.science.oregonstate.edu/ocean.productivity/>). Using the monthly data
466 for years 2005 to 2010 (in hdf format), we imported and converted those data into
467 ArcGIS. We then calculated yearly average and finally an average for all these years.
468 We used a 100km buffer around each of our sites and examined the average
469 productivity within that radius. Note that ocean productivity estimates are less
470 accurate for nearshore environments, but we used the best available data.

471

472 Analyses

473 We first looked for collinearity among our covariates using bivariate correlations and
474 variance inflation factor estimates (Extended Data Fig. 4, Extended Data Table 7).
475 This led to the exclusion of several covariates (not described above): i) *Geographic*
476 *Basin* (Tropical Atlantic, western Indo-Pacific, Central Indo-Pacific, or eastern Indo-
477 Pacific); ii) *Gross Domestic Product* (purchasing power parity); iii) *Rule of Law*
478 (World Bank governance index); iv) *Control of Corruption* (World Bank governance
479 index); and v) *Sedimentation*. Additionally, we removed an index of climate stress,
480 developed by Maina et al.⁴⁹, which incorporated 11 different environmental
481 conditions, such as the mean and variability of sea surface temperature due to
482 repeated lack of convergence for this parameter in the model, likely indicative of
483 unidentified multi-collinearity. All other covariates had correlation coefficients 0.7 or
484 less and Variance Inflation Factor scores less than 5 (indicating multicollinearity was
485 not a serious concern). Care must be taken in causal attribution of covariates that were
486 significant in our model, but demonstrated colinearity with candidate covariates that
487 were removed during the aforementioned process. Importantly, the covariate that

488 exhibited the largest effect size in our model, market gravity, was not strongly
489 collinear with other candidate covariates.

490

491 To quantify the multi-scale social, environmental, and economic factors affecting reef
492 fish biomass we adopted a Bayesian hierarchical modelling approach that explicitly
493 recognized the three scales of spatial organization: reef (j), site (k), and nation/state
494 (s).

495

496 In adopting the Bayesian approach we developed two models for inference: a null
497 model, consisting only of the hierarchical units of observation (i.e. intercepts-only)
498 and a full model that included all of our covariates (drivers) of interest. Covariates
499 were entered into the model at the relevant scale, leading to a hierarchical model
500 whereby lower-level intercepts (averages) were placed in the context of higher-level
501 covariates in which they were nested. We used the null model as a baseline against
502 which we could ensure that our full model performed better than a model with no
503 covariate information. We did not remove 'non-significant' covariates from the model
504 because each covariate was carefully considered for inclusion and could therefore
505 reasonably be considered as having an effect, even if small or uncertain; removing
506 factors from the model is equivalent to fixing parameter estimates at exactly zero - a
507 highly-subjective modelling decision after covariates have already been selected as
508 potentially important⁵⁰.

509

510 The full model assumed the observed, environmental-scale observations of fish
511 biomass (y_{ijks}) were modelled using a noncentral-T distribution, allowing for fatter
512 tails than typical log-normal models of reef fish biomass³².

513

$$514 \quad \log(y_{ijks}) \sim \text{Noncentral}T(\mu_{ijks}, \tau_{reef}, 3.5)$$

$$515 \quad \mu_{ijks} = \beta_{0jks} + \beta_{reef} X_{reef}$$

$$516 \quad \tau_{reef} \sim U(0,100)^{-2}$$

517

518 with X_{reef} representing the matrix of observed environmental-scale covariates and

519 β_{reef} the array of estimated reef-scale parameters. The τ_{reef} (and all subsequent τ 's)

520 were assumed common across observations in the final model and were minimally

521 informative⁵⁰. Using a similar structure, the environmental-scale intercepts (β_{0jks})

522 were structured as a function of site-scale covariates (X_{sit}):

523

$$524 \quad \beta_{0jks} \sim N(\mu_{jks}, \tau_{sit})$$

$$525 \quad \mu_{jks} = \gamma_{0ks} + \gamma_{sit} X_{sit}$$

$$526 \quad \tau_{sit} \sim U(0,100)^{-2}$$

527

528 with γ_{sit} representing an array of site-scale parameters. Building upon the hierarchy,

529 the site-scale intercepts (γ_{0ks}) were structured as a function of state-scale covariates

530 (X_{sta}):

531

$$532 \quad \gamma_{0ks} \sim N(\mu_{ks}, \tau_{sta})$$

$$533 \quad \mu_{ks} = \gamma_{0s} + \gamma_{sta} X_{sta}$$

$$534 \quad \tau_{sta} \sim U(0,100)^{-2}$$

535

536 Finally, at the top scale of the analysis we allowed for a global (overall) estimate of

537 average log-biomass (μ_0):

538

539 $\gamma_{0s} \sim N(\mu_0, \tau_{glo})$

540 $\mu_0 \sim N(0.0, 1000)$

541 $\tau_{glo} \sim U(0,100)^{-2}$.

542

543 The relationships between fish biomass and environmental, site, and state scale
544 drivers was carried out using the PyMC package⁵¹ for the Python programming
545 language, using a Metropolis-Hastings (MH) sampler run for 10^6 iterations, with a
546 900,000 iteration burn in, leaving 10,000 samples in the posterior distribution of each
547 parameter; these long burn-in times are often required with a complex model using
548 the MH algorithm. Convergence was monitored by examining posterior chains and
549 distributions for stability and by running multiple chains from different starting points
550 and checking for convergence using Gelman-Rubin statistics⁵² for parameters across
551 multiple chains; all were at or close to 1, indicating good convergence of parameters
552 across multiple chains.

553

554 *Overall model fit*

555

556 We conducted posterior predictive checks for goodness of fit (GoF) using Bayesian p-
557 values⁴⁰ (BpV), whereby fit was assessed by the discrepancy between observed or
558 simulated data and their expected values. To do this we simulated new data (y_i^{new}) by
559 sampling from the joint posterior of our model (θ) and calculated the Freeman-Tukey
560 measure of discrepancy for the observed (y_i^{obs}) or simulated data, given their expected
561 values (μ_i):

562

563 $D(y|\theta) = \sum_i (\sqrt{y_i} - \sqrt{\mu_i})^2$

564

565 yielding two arrays of median discrepancies $D(y^{obs}/\theta)$ and $D(y^{new}/\theta)$ that were then used
566 to calculate a BpV for our model by recording the proportion of times $D(y^{obs}/\theta)$ was
567 greater than $D(y^{new}/\theta)$ (Extended Data Fig. 5). A BpV above 0.975 or under 0.025
568 provides substantial evidence for lack of model fit. Evaluated by the Deviance
569 Information Criterion (DIC), the full model greatly outperformed the null model
570 ($\Delta DIC=472$).

571

572 To examine homoscedasticity, we checked residuals against fitted values. We also
573 checked the residuals against all covariates included in the model, and several
574 covariates that were not included in the model (primarily due to collinearity),
575 including: 1) *Atoll* - A binary metric of whether the reef was on an atoll or not; 2)
576 *Control of Corruption*: Perceptions of the extent to which public power is exercised
577 for private gain, including both petty and grand forms of corruption, as well as
578 'capture' of the state by elites and private interests. Derived from the World Bank
579 survey on governance; 3) *Geographic Basin*- whether the site was in the Tropical
580 Atlantic, western Indo-Pacific, Central Indo-Pacific, or eastern Indo-Pacific; 4)
581 *Connectivity* – we examined 3 measures based on the area of coral reef within a
582 30km, 100km, and 600km radius of the site; 5) *Sedimentation*; 6) *Coral Cover* (which
583 was only available for a subset of the sites); 7) *Climate stress*⁴⁹; and 8) *Census*
584 *method*. The model residuals showed no patterns with these eight additional
585 covariates, suggesting they would not explain additional information in our model.

586

587 *Bright and dark spot estimates*

588 Because the performance of site scale locations are of substantial interest in
589 uncovering novel solutions for reef conservation, we defined bright and dark spots at
590 the site scale. To this end, we defined bright (or dark) spots as locations where
591 expected site-scale intercepts (γ_{0ks}) differed by more than two standard deviations
592 from their nation/state-scale expected value (μ_{ks}), given all the covariates present in
593 the full hierarchical model:

$$594 SS_{spot} = |(\mu_{ks} - \gamma_{0ks})| > 2[SD(\mu_{ks} - \gamma_{0ks})].$$

595 This, in effect, probabilistically identified the most deviant sites, given the model,
596 while shrinking sites toward their group-level means, thereby allowing us to
597 overcome potential bias due to low and varying sample sizes that can lead to extreme
598 values from chance alone. As a conservative precaution, we did not consider a site a
599 bright or dark spot if the group-level (i.e. nation/state) mean had fewer than 5
600 estimates (sites).

601

602 *Analysing conditions at bright spots*

603 We surveyed data providers and other experts about key social, institutional, and
604 environmental conditions at the 15 bright spots, 35 dark spots, and 14 sites that
605 performed most closely to model specifications. Research on bright spots in
606 agricultural development¹³ highlights several potential mechanisms, which formed the
607 basis of our exploration. These include:

608 i) *Environmental/ecological processes* (e.g. recruitment & connectivity). We
609 examined whether sites were within 5km of mangroves and deep-water
610 refuges, and whether there had been any major environmental disturbances

611 such as coral bleaching, tsunami, and cyclones within the past 5 years. All
612 environmental conditions were recorded as present/absent;

613 ii) *Social and institutional conditions.* We examined the presence of
614 customary management institutions such as taboos and marine tenure
615 institutions, whether there was a high level of engagement by local people
616 in management, whether there was high levels of dependence on marine
617 resources (whether a majority of local residents depend on reef fish as a
618 primary source of food or income). All social and institutional conditions
619 were recorded as presence/absence. Dependence on resources and
620 engagement were limited to sites that had adjacent human populations. All
621 other conditions were recorded regardless of whether there is an adjacent
622 community;

623 iii) *Technological use/innovation.* We examined the presence of motorised
624 vessels, intensive capture equipment (such as beach seine nets, surround
625 gill nets, and muro-ami nets), and storage capacity (i.e. freezers); and

626 iv) *External influences* (such as donor-driven projects). We examined the
627 presence of NGOs, fishery development projects, development initiatives
628 (such as alternative livelihoods), and fisheries improvement projects. All
629 external influences were recorded as present/absent then summarised into
630 a single index of whether external projects were occurring at the site.

631

632 To test for associations between these mechanisms and whether sites were more or
633 less bright, we used two complementary approaches. The link between the
634 presence/absence of the aforementioned mechanisms and whether a site was bright,
635 average, or dark was assessed using a Fisher's Exact Test. Then we tested whether the

636 mean deviation in fish biomass from expected was similar between sites with
637 presence or absence of the mechanisms in question (i.e. the presence or absence of
638 marine tenure/taboo) using an ANOVA assuming unequal variance. The two tests
639 yielded similar results, but provide slightly different ways to conceptualise the issue,
640 the former is correlative while the latter explains brightness based on mechanisms, so
641 we provide both (Figure 2, Extended Data Fig. 6).

798 **Extended Data Tables**

799

800 **Extended Data Table 1 | Summary of social and environmental covariates.**

801 Further details can be found in the Supplemental Online Methods. The smallest scale

802 is the individual reef. Sites consist of clusters of reefs within 4km of each other.

803 Nation/states generally correspond to country, but can also include or territories or

804 states, particularly when geographically isolated (e.g. Hawaii).

805

Covariate	Description	Scale	Key data sources
Local population growth	Difference in local human population (i.e. 100km buffer around our sites) between 2000-2010	Site	Socioeconomic Data and Application Centre (SEDAC) gridded population of the world database ³⁶
‘Gravity’ of major markets within 500km	The population of the major market divided by the squared travel time between the reef sites and the market. This value was summed for all major markets within 500km of the site.	Site	Human population size, land cover, road networks, coastlines
‘Gravity’ of the closest human settlement	The population of the nearest human settlement divided by the squared travel time between the reef site and the settlement.	Site	Human population size, land cover, road networks, coastlines

Protection status	Whether the reef is openly fished, restricted (e.g. effective gear bans or effort restrictions), or unfished	Reef	Expert opinion, global map of marine protected areas.
Human Development index	A summary measure of human development encompassing: a long and healthy life, being knowledgeable and have a decent standard of living. We used linear and quadratic functions for HDI.	Nation/state	United Nations Development Programme
Population Size	Total population size of the jurisdiction	Nation/state	World Bank, census estimates, Wikipedia
Tourism	Proportion of tourist visitors to residents	Nation/state	World Tourism Organization's Compendium of Tourism Statistics, census estimates
Voice and accountability	Perceptions of the extent to which a country's citizens are able to participate in selecting their government.	Nation/state	World Bank

Fish landings	Landings of reef fish (tons) per Km ² of reef	Nation/ state	Teh et al. ⁴⁷
National fisheries poaching	Results from survey of national fisheries managers about levels of compliance with national fisheries regulations	Nation/ state	Mora et al. ⁵³
Climate stress	A composite metric comprised of 11 different environmental variables that are related to coral mortality from bleaching	Site	Maina et al. ⁴⁹
Productivity	The average (2005-2010) ocean productivity in mg C / m ² / day	Site	http://www.science.oregonstate.edu/ocean.productivity/
Habitat	Whether the reef is a slop, crest, flat, or back reef/lagoon	Reef	Primary data
Depth	Depth of the ecological survey (<4m, 4.1-10m, >10m)	Reef	Primary data

807 **Extended Data Table 2 | List of ‘Nation/states’ covered in study and their**
808 **respective average biomass (plus or minus standard error)** In most cases,
809 nation/state refers to an individual country, but can also include states (e.g. Hawaii or
810 Florida), territories (e.g. British Indian Ocean Territory), or other jurisdictions. We
811 treated the NW Hawaiian Islands and Farquhar as separate ‘nation/states’ from
812 Hawaii and Seychelles, respectively, because they are extremely isolated and have
813 little or no human population. In practical terms, this meant different values for a few
814 nation/state scale indicators that ended up having relatively small effect sizes, anyway
815 (Fig. 1b): Population, tourism visitations, and in the case of NW Hawaiian Island, fish
816 landings.
817

Nation/states	Average biomass	(± SE)
American Samoa	235.93	(± 17.75)
Australia	735.01	(± 136.85)

823 **Extended Data Table 4| List of fish families included in the study, their common**
 824 **name, and whether they are commonly targeted in artisanal coral reef fisheries.**

825 Note: Targeting of reef fishes can vary by location due to gear, cultural preferences,
 826 and a range of other considerations.

827

Fish family	Common family name	Fishery target
Acanthuridae	Surgeonfishes	Target
Balistidae	Triggerfishes	Non-target
Diodontidae	Porcupinefishes	Non-target
Ephippidae	Batfishes	Target
Haemulidae	Sweetlips	Target
Kyphosidae	Drummers	Target
Labridae	Wrasses and Parrotfish	Target >20cm
Lethrinidae	Emperors	Target
Lutjanidae	Snappers	Target
Monacanthidae	Filefishes	Non-target
Mullidae	Goatfishes	Target
Nemipteridae	Coral Breams	Target
Pinguipedidae	Sandperches	Non-target
Pomacanthidae	Angelfishes	Target >20cm
Serranidae	Groupers	Target
Siganidae	Rabbitfishes	Target
Sparidae	Porgies	Target
Synodontidae	Lizardfishes	Non-target
Tetraodontidae	Pufferfishes	Non-target
Zanclidae	Moorish Idol	Non-target

M10	Population of the nearest large peri-urban area (75 people/km ²)	2822.2	155.8
M0	Intercept only	2827.7	161.27

841

842 **Extended Data Figure Legends**

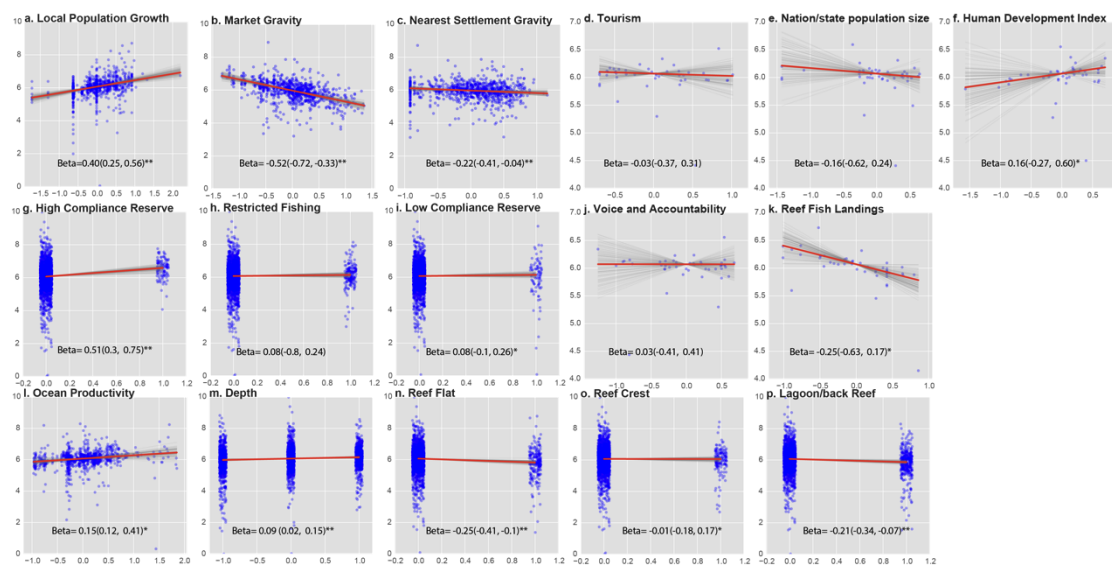

843

844

845 **Extended Data Figure 1** | a) A heuristic of the gravity concept where interactions
846 between people and reefs are a function of population size (p) and the time it takes to
847 travel to the reef (tt). Beginning in the 1800s, the concept of ‘gravity’ has been
848 applied to measure economic interactions, migration patterns, and trade flows^{29,54-56}.
849 Drawing on an analogy from Newton’s Law of Gravitation, the gravity concept
850 predicts that interactions between two points are positively related to their mass (i.e.,
851 population) and inversely related to the distance between them. Here, we adapt the
852 gravity concept to examine interactions between people and reefs. We posit that
853 human interactions with a reef will be a function of the population of a place (p)
854 divided by the squared time it takes to travel (tt) to the reefs (i.e. travel time). Thus,
855 gravity values could be similar for places that are large but far from the reefs (e.g. p_x
856 = 30,000 people, $tt_x= 10$ hours) as to those with small populations that are close to the
857 reef (e.g. $p_y = 300$ people, $tt_y = 1$ hour). We used travel time instead of linear distance

858 to account for the differences incurred by travelling over different surfaces (e.g.
859 water, roads, tracks—see Methods). We developed gravity measures for the nearest
860 human settlement and for the nearest major market (defined as provincial capitals,
861 ports, and other large, populated places- see Methods). b) Gravity isoclines along
862 gradients of population size and travel time.
863

864 **Extended Data Figure 2 | Marginal relationships between reef fish biomass and**
 865 **site-level social drivers.** a) local population growth, b) market gravity, c) nearest
 866 settlement gravity, d) tourism, e) nation/state population size, f) Human development
 867 Index, g) high compliance marine reserve (0 is fished baseline), h) restricted fishing
 868 (0 is fished baseline), i) low compliance marine reserve (0 is fished baseline), j) voice
 869 and accountability, k) reef fish landings, l) ocean productivity; m) depth (-1= 0-4m,
 870 0= 4-10m, 1=>10m), n) reef flat (0 is reef slope baseline), o) reef crest flat (0 is reef
 871 slope baseline), p) lagoon/back reef flat (0 is reef slope baseline). All X variables are
 872 standardized. ** 95% of the posterior density is either a positive or negative direction
 873 (Box 1); * 75% of the posterior density is either a positive or negative direction.

877
878
879
880
881
882
883

Extended Data Figure 3 | Market gravity and fish biomass. Relationship between market gravity and a) reef fish biomass; b) targeted reef fish biomass (using fish families targeted by artisanal fisheries specified in Extended Data Table 2); c) non-target reef fish biomass. The strong relationship between gravity and reef fish biomass is very similar for the biomass of fishes generally targeted by artisanal fisheries, but very different for non-target fishes. This suggests that the relationship between market gravity and fish biomass is primarily driven by fishing, rather than other potential human impacts of urban areas (sedimentation, nutrients, pollution, etc.).

884 **Extended Data Figure 4| Correlation plot of candidate continuous covariates before accounting for colinearity (Extended Data Table 7).**
885 Colinearity between continuous and categorical covariates (including biogeographic region, habitat, protection status, and depth) were analysed
886 using boxplots.
887

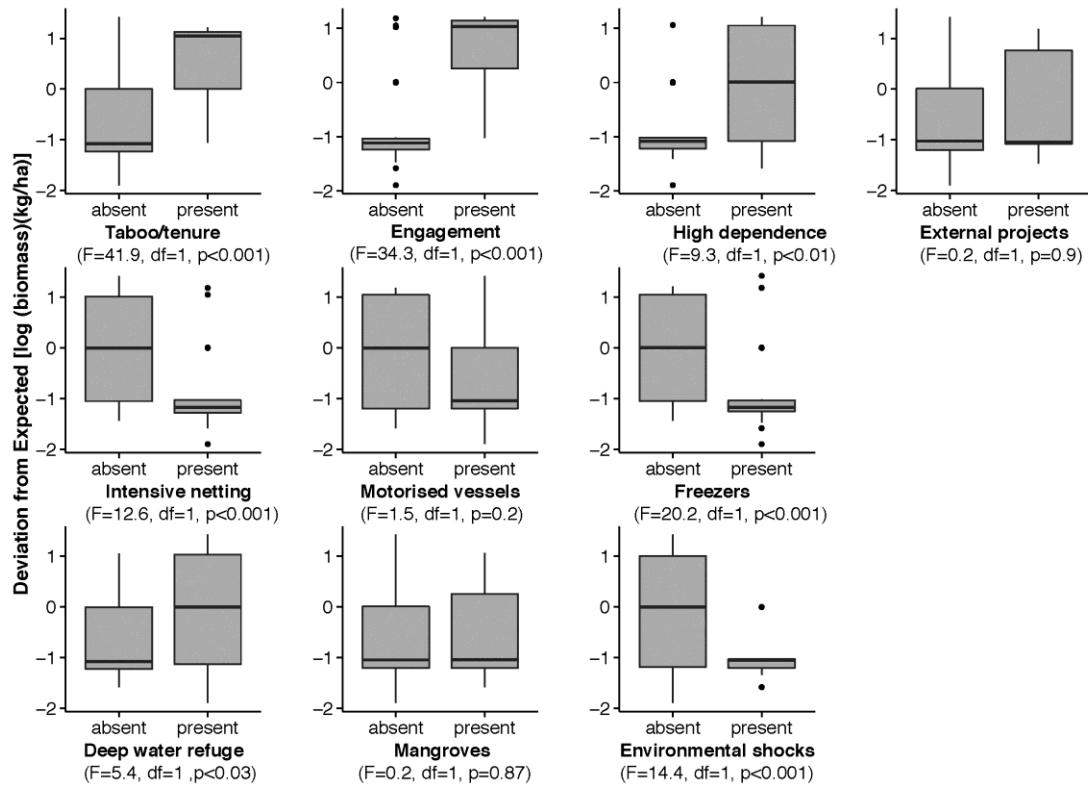

889

890 **Extended Data Figure 5 | Model fit statistics.** Bayesian p Values (BpV) for the full
891 model indicating goodness of fit, based on posterior discrepancy. Points are Freeman-
892 Tukey differences between observed and expected values, and simulated and expected
893 values. Plot shows no evidence for lack of fit between the model and the data.
