Maternal and perinatal outcomes by planned place of birth among women with low-risk pregnancies in high-income countries: A systematic review and meta-analysis

Abstract

Background

The comparative safety of different birth settings is widely debated. Comparing research across high-income countries is complex, given differences in maternity service provision, data discrepancies, and varying research techniques and quality. Studies of births planned at home or in birth centres have reported both better and poorer outcomes than planned hospital births. Previous systematic reviews have focused on outcomes from either birth centres or home births, with inconsistent attention to quality appraisal. Few have attempted to synthesise findings.

Objective

To compare maternal and perinatal outcomes from different places of birth via a systematic review of high-quality research, and meta-analysis of appropriate data (Prospero registration CRD42016042291).

Design
Reviewers searched CINAHL, Embase, Maternity and Infant Care, Medline and PsycINFO databases to identify studies comparing selected outcomes by place of birth among women with low-risk pregnancies in high-income countries. They critically appraised identified studies using an instrument specific to birth place research and then combined outcome data via meta-analysis, using RevMan software.

**Findings**

Twenty-eight articles met inclusion criteria, yielding comparative data on perinatal mortality, mode of birth, maternal morbidity and/or NICU admissions. Meta-analysis indicated that women planning hospital births had statistically significantly lower odds of normal vaginal birth than in other planned settings. Women experienced severe perineal trauma or haemorrhage at a lower rate in planned home births than in obstetric units. There were no statistically significant differences in infant mortality by planned place of birth, although most studies had limited statistical power to detect differences for rare outcomes. Differences in location, context, quality and design of identified studies render results subject to variation.

**Conclusions and implications for practice**

High-quality evidence about low-risk pregnancies indicates that place of birth had no statistically significant impact on infant mortality. The lower odds of maternal morbidity and obstetric intervention support the expansion of birth centre and home birth options for women with low-risk pregnancies.
Keywords

Home childbirth, birthing centres, obstetric delivery, pregnancy outcome, infant mortality, postpartum haemorrhage
Introduction

The universal importance of maternal and newborn well-being is unquestioned. However, the impact of place of birth on safety and well-being is widely debated globally. Debate is fuelled by divergent conclusions from research on planned place of birth (de Vries et al. 2013) and is further complicated by national and regional variation in provision of maternity care across birth places.

Women are increasingly seeking greater choice in birth place, including options other than hospitals that offer fewer interventions and greater autonomy (Vedam, Stoll, et al. 2017). Yet, researchers vary in their conclusions about outcomes from different places of birth. Consequently, there is keen interest in reliable research evidence comparing maternal and perinatal outcomes by place of birth, especially amongst clinicians, policy-makers, and childbearing women and their families. There is particular attention devoted to home as a safe place of birth. Study findings must take account not only of whether the mother and infant survive but also how well mother and infant thrive in different birthplaces. Diverse study designs and methods, and contradictory research findings create difficulty in synthesising outcomes to inform clinical decisions. Accordingly, government policy and professional guidelines in different countries vary in their support for birth centres and home births. Variation reflects differing beliefs about autonomy, safety, risk and childbirth, together with differing interpretations of the body of existing research (Roome & Welsh 2015).

Variation in birth setting

In many high-income countries, most women give birth in hospital. Access to alternative birth places varies within and between countries, although usually limited. In the Netherlands approximately 20% of births take place at home; elsewhere the proportion of planned home births
in high-income countries ranges between 0.3% in Australia (Hilder et al. 2014) and 3.3% in New Zealand (Shaw et al. 2016). Similarly, the rate of births in midwife-led birth centres (a term encompassing various models) varies from approximately 0.5% in the United States (MacDorman & Declercq 2016) to over 10% in New Zealand and the Netherlands (Shaw et al. 2016) and 11% in England (National Audit Office 2013). Variation in birthplace options is affected by the status, scope and role of the midwife in different jurisdictions, licensing and insurance issues, the extent of integration between maternity care options, funding issues and other sociocultural factors (Benoit et al. 2005; De Vries et al. 2002; Vedam et al. 2018).

The debate on safety

Several recent studies in high-income regions compared outcomes from births planned in hospitals and at home. They found no significant difference in risk of adverse perinatal outcomes for planned home births among women with low-risk pregnancies (de Jonge et al. 2015; de Jonge et al. 2009; Hutton et al. 2016; Janssen et al. 2009) and among low-risk parous women (Birthplace in England Collaborative 2011; Homer et al. 2014). Similarly, studies found no significant differences in adverse outcomes between births planned in labour wards and in birth centres (Birthplace in England Collaborative 2011; Gottvall et al. 2005; Homer et al. 2014; Laws, Tracy & Sullivan 2010). Further, many studies identified lower rates of intervention and/or maternal morbidity in births planned in birth centres and at home, compared with hospital births.

However, other investigators reported higher rates of adverse perinatal outcomes in planned home births than in planned hospital births (Grunebaum et al. 2014; Pang et al. 2002; Snowden et al. 2015; Wax, Lucas, et al. 2010). Some of these findings were reported in countries where skilled birth attendants are not universally integrated across birth settings into regional health systems (e.g. Chang & MacOnes 2011; Kennare et al. 2010; Snowden et al. 2015). Other results were from
population-based studies that combined pregnancies with different levels of risk or used unreliable data sources for the reported outcome (e.g. Cheng et al. 2013; Evers et al. 2010; Grunebaum et al. 2013; Kennare et al. 2010; Pang et al. 2002; Wax, Pinette, et al. 2010). Others combined data from births with skilled and unskilled birth attendants (e.g. Chang & MacOnes 2011; Malloy 2010). A large English study reported a small but statistically significant increase in adverse results on a composite primary perinatal outcome (including both mortality and morbidity) among nulliparous women planning home births compared with those planning a hospital birth (Birthplace in England Collaborative Group 2011).

Variation in the design and quality of research on place of birth inhibits the development of universally acceptable recommendations for provision of services across settings (Gyte et al. 2009; Michal et al. 2011; Nove, Berrington & Matthews 2012b; Vedam 2003; Vedam, Schummers & Fulton 2013).

**Methodological challenges in research about place of birth**

Researchers have delineated and discussed the unique features of studies into place of birth (Declercq 2013; Leslie & Romano 2007; Nove, Berrington & Matthews 2012b; Olsen & Clausen 2012; Vedam 2003; Zielinski, Ackerson & Kane Low 2015). These features include appropriately identifying intended (as distinct from actual) birth place, ensuring equivalence of risk status, controlling for confounding and mediating factors, dealing with adverse events that would have occurred regardless of setting (especially related to congenital abnormalities), and accounting for different providers in countries with different models of maternity provision.

When comparing outcomes across places of birth, consistent, standardised inclusion criteria across cohorts, reliable sampling methods, and relevant outcome measures are all imperative. For example, some research on place of birth is compromised by amalgamating data from unplanned
home births (without skilled birth attendants) and from planned births at home within integrated
maternity systems (Gyte et al. 2010; Kirby & Frost 2011; Michal et al. 2011). All these factors, as
well as the limits to randomisation, complicate appraisals of research quality and risk of bias

Further, adequate sample sizes are essential to allow for comparisons between settings, especially
when exploring rare outcomes such as mortality and severe morbidity. Relatively small numbers of
women choose to give birth in birth centres or at home in most high-income countries. Typically,
datasets with sufficient power can only be generated by large population-based studies conducted
over several years, notwithstanding the limitations of using registry-based data (de Jonge et al.
2017), or through meta-analysis, where possible. Some studies have utilised a ‘composite
outcome’ to group data on uncommon adverse outcomes to improve statistical power (Birthplace
in England Collaborative Group et al. 2011). Finally, the diverse context of maternity provision in
different countries generates inconsistencies in data availability, inclusion criteria and key
definitions, further complicating research in this field.

Synthesising research findings

There have been few Cochrane reviews of place of birth outcomes. Olsen and Clausen attempted a
systematic review comparing planned home versus hospital birth (2012) and were able to identify
only one small study (n=11) that met inclusion criteria. Noting difficulties with recruiting women
who will consent to randomisation, their discussion highlighted the importance of well-designed
population-based observational studies. Another Cochrane review (Hodnett, Downe & Walsh
2012) incorporated 10 trials comparing ‘alternative settings for birth’ with conventional hospital
labour wards, of which five examined alongside midwifery units. This review found no impact on
adverse outcomes for mothers or infants across included settings, but women allocated to
alternative settings had higher rates of spontaneous vaginal births and breastfeeding at six to eight weeks, and lower rates of obstetric intervention than women giving birth in hospital units (Hodnett, Downe & Walsh 2012).

Other research syntheses about outcomes by place of birth have involved largely narrative analysis. Some compared data from hospital births with home births (Elder, Alio & Fisher 2016; Fullerton, Navarro & Young 2007; Leslie & Romano 2007; McIntyre 2012; Stotland & Declercq 2002; Zielinski, Ackerson & Kane Low 2015); others compared births in hospitals with birth centres (Alliman & Phillippi 2016; Dixon et al. 2012; McIntyre 2012; Muthu & Fischbacher 2004; Stewart et al. 2005; Stotland & Declercq 2002; Walsh & Downe 2004).

The varying quality of research has been a recurring theme in reviews (Campbell & MacFarlane 1986; Elder, Alio & Fisher 2016; McIntyre 2012; Olsen 1997; Vedam, Schummers & Fulton 2013). Some authors have specifically concluded that the limited quality or comparability of studies precludes undertaking meta-analysis (Blix et al. 2014; Stewart et al. 2005; Walsh & Downe 2004). Some systematic reviews indicate methods used to assess potential bias in selected studies (Alliman & Phillippi 2016; Blix et al. 2014; Stewart et al. 2005; Walsh & Downe 2004), although other reviews do not indicate how quality was determined. One systematic review and meta-analysis comparing planned home births and hospital births (Wax, Lucas, et al. 2010) reported that study quality was evaluated using a published instrument (Zaza et al. 2000) but did not report on the quality assessment of included studies. This meta-analysis has been widely criticised for methodological flaws (Gyte et al. 2010; Kirby & Frost 2011; Michal et al. 2011).

We did not identify any systematic review or meta-analysis that examined outcomes from studies across three places of birth (home, birth centre, hospital), using a validated rating tool to appraise the quality of included studies.
Objectives

This systematic review addressed the question: are perinatal and maternal outcomes significantly different from births planned at home, in birth centres or hospitals, for women with low-risk pregnancies? We reviewed original research from high-income countries (World Bank 2016) using a birthplace-specific quality appraisal instrument (Vedam, Rossiter, et al. 2017), and undertook meta-analysis of outcome data where possible.

Methods

The review examined the effect of birth place as distinct from model of maternity care, although often closely linked. The definition of place of birth varied between studies, depending on data availability, regional differences in provision and study design. We registered our protocol with Prospero international register of systematic reviews (http://www.crd.york.ac.uk/PROSPERO/) in July 2016 (CRD42016042291). This paper follows the PRISMA guidelines for reporting systematic reviews and meta-analyses (Moher, Liberati, Tetzlaff, Altman, et al. 2009).

Eligibility criteria

The systematic review included articles:

- published in peer-reviewed journals between 2000 and 2016;
- comparing outcomes from two or more places of birth;
- written in English.

We included articles which provided evidence on one or more of nine outcomes addressing important dimensions of perinatal mortality and morbidity, mode of birth and maternal morbidity (regardless of other outcomes examined):
1. intrapartum stillbirth
2. early neonatal mortality 0-7 days
3. admission to neonatal intensive care unit (NICU)
4. normal vaginal birth
5. instrumental birth
6. caesarean section
7. intact perineum after vaginal birth
8. severe perineal trauma (3rd or 4th degree tear) after vaginal birth
9. postpartum haemorrhage (PPH) >1000mL.

Table 1 indicates inclusion criteria following a framework comprising population, intervention, comparison, outcomes and study design (PICOS) (Moher, Liberati, Tetzlaff & Altman 2009), giving examples of excluded study types.

INSERT TABLE 1 HERE

Information sources

We searched five databases during May 2016: CINAHL, Embase, Maternity and Infant Care, Medline and PsycINFO. We further scrutinised reference lists manually to identify other potential articles, and set up alerts from the databases used to receive notification of relevant articles published after the main data extraction. We updated the search in January 2017, to fully cover the period 2000-2016.

Search strategy
The review used a combination of search terms (Box 1) encompassing different concepts. The ‘birth place terms’ in column A were all combined with the Boolean term OR, as were all ‘outcome terms’ in column B. The resulting searches A and B were then combined with AND.

**Study selection**

Two researchers searched electronic databases and screened the results for eligibility. We removed duplicates, screened titles to remove those clearly out of scope and then reviewed abstracts to assess eligibility. Both then read the remaining 86 articles to further determine eligibility, and resolved any disagreement about inclusion by discussion. In ensuring that selected studies contained relatively comparable risk levels, we excluded those including women with even one previous caesarean section (CS) (Hutton et al. 2016; Janssen et al. 2009). Supplementary Table S1 indicates reasons for excluding 58 articles from the systematic review following this close reading. Figure 1 illustrates the study selection process.

**Study appraisal (risk of bias)**

We assessed study quality using the Birth Place Research Quality (ResQu) Index (see Supplementary Figure S19), a newly developed critical appraisal system. This instrument was developed specifically to appraise studies that compare different birth settings, and takes account of the unique characteristics of place of birth research. Development and content validation by an international panel of experts are described elsewhere (Vedam, Rossiter, et al. 2017). The instrument provides a quantitative summary score based on 27 criteria to rate the quality of
research evidence at study level: high (scores of 75% and above), moderate (65-74%) and low (less than 65%).

Two researchers read the remaining 28 articles and rated them using the ResQu Index, discussing any diverging scores until reaching consensus. During meta-analysis, sensitivity analyses eliminated studies that scored less than 75% to explore the impact of research quality on identified outcomes.

**Data items**

Box 2 defines the data items.

---

**Data collection process**

Two researchers independently extracted the raw data for the nine outcomes from the 28 articles, ensuring consistency with our definitions (Box 2). These were recorded on a specifically-developed extraction form (Supplementary Table S2). We endeavoured to locate additional data for this systematic review, including seeking supplementary tables. At times, the extracted data differed from the published rates; for instance, for studies examining perineal outcomes, we ensured that the denominator included only vaginal births. We resolved any discrepancies by careful discussion of the studies’ methodology and results.

**Summary measures**
Selected studies presented outcome data in different ways, most commonly (adjusted) odds ratios (OR) but also relative risk or as percentages. Supplementary Table S3 presents further detail on the statistical techniques and findings from the selected studies on outcomes relevant to this review.

**Synthesis of results (meta-analysis)**

Data on the nine outcomes (where available) were entered into the RevMan software (The Nordic Cochrane Centre 2014) to calculate estimated ORs for each outcome, with a 95% confidence interval (CI). This used the random effects statistical model given the varying study designs and heterogeneity in findings. Few individual studies included in the meta-analyses had sample sizes of sufficient power to detect meaningful differences in rare outcomes such as perinatal mortality (de Jonge et al. 2015; van der Kooy et al. 2011).

Where there were zero events reported in a study, individual odds ratios are not calculable, but these data are included in the pooled denominator to calculate the overall odds ratio for that outcome. Occasionally we have included studies which did not define mortality variables fully but where zero events in both cohorts (Gaudineau et al. 2013; Halfdansdottir et al. 2015; Homer et al. 2000; Overgaard et al. 2011) meant that a specific definition (e.g. neonatal death) was not required as the result would have been zero regardless of the actual definition.

Some articles reported data from the same study or utilise the same (or overlapping) datasets. For instance, several studies use data from the Netherlands Perinatal Registry for intersecting periods (de Jonge et al. 2013; van der Kooy et al. 2011; Wiegerinck et al. 2015). Similarly, two New Zealand studies used data from the same dataset for the years 2006-2007 (Davis et al. 2011; Dixon et al. 2014). We only used one source in each meta-analysis. Two selected studies were not included in
any meta-analysis because they used data which overlapped other studies (Overgaard, Fenger-Grøn & Sandall 2012; van der Kooy et al. 2011). Another study did not present raw data from the lowest-risk cohorts (Pang et al. 2002). Other studies were excluded from specific meta-analyses because they used different definitions from ours on individual variables. For instance, regarding perinatal mortality, the Birthplace in England study used a composite neonatal outcome rather than stillbirth or early neonatal death (Birthplace in England Collaborative Group 2011). Others presented data on neonatal death up to 28 days rather than seven (Davis et al. 2011; Laws, Tracy & Sullivan 2010) or combined data on intrapartum stillbirth and neonatal death (Dixon et al. 2014; van der Kooy et al. 2011). Some studies did not provide sufficient specificity on critical terms, such as ‘stillbirth’ (Burns et al. 2012; Dixon et al. 2014; Laws, Tracy & Sullivan 2010). A number of studies were excluded from the PPH meta-analysis because they only presented data on blood loss over 500mL (Blix et al. 2012; Gaudineau et al. 2013; Miller & Skinner 2012; Prelec, Verdenik & Poat 2014) or over 300mL (Byrne, Crowther & Moss 2000).

**Additional analyses**

To address the unavoidable heterogeneity of the selected studies, we conducted sensitivity analyses, excluding studies that achieved less than 75% in the ResQu Index. The results of the sensitivity analyses are reported beside the main findings. For perinatal outcomes, we also eliminated data from studies that did not specifically exclude known congenital abnormalities and conducted further analysis by parity when data were available from studies of planned home births. (Data on planned births in birth centre were insufficient to stratify by parity.) In assessing birth centre outcomes, separate analyses compared data from FMUs and AMUs. In studies of birth centres in Australia (Homer et al. 2014; Laws, Tracy & Sullivan 2010), the meta-analysis assumed these to be AMUs. However, it is possible that data include a small number of FMU births during
the periods studied; there are very few FMUs in Australia and some units closed during the study period (Monk et al. 2013).

Results

Study selection

Initial searching identified 4059 records across five databases and another eight manually. Figure 1 illustrates the process of screening and reviewing articles to meet inclusion criteria. In the final stage, two reviewers read the remaining 86 articles and excluded 58 (Supplementary Table 1).

Study characteristics

Twenty-eight eligible articles from 26 studies remained, published 2000-2016. Table 2 summarises PICOS with further detail in Supplementary Table 2. Five studies originated in Australia (Byrne, Crowther & Moss 2000; Homer et al. 2000; Homer et al. 2014; Laws, Tracy & Sullivan 2010; Ryan & Roberts 2005), five in the Netherlands (Bolten et al. 2016; de Jonge et al. 2015; de Jonge et al. 2013; van der Kooy et al. 2011; Wiegerinck et al. 2015), three in the United Kingdom (Birthplace in England Collaborative Group 2011; Burns et al. 2012; Nove, Berrington & Matthews 2012a), six in Nordic countries (Bernitz et al. 2011; Blix et al. 2012; Eide, Nilsen & Rasmussen 2009; Halfdansdottir et al. 2015; Overgaard, Fenger-Gron & Sandall 2012; Overgaard et al. 2011), two in other European countries (Gaudineau et al. 2013; Prelec, Verdenik & Poat 2014), four in New Zealand (Davis et al. 2012; Davis et al. 2011; Dixon et al. 2014; Miller & Skinner 2012), two in the USA (Pang et al. 2002; Thornton et al. 2016) and one in Japan (Hiraizumi & Suzuki 2013). Research design included two randomised controlled trials (both of AMUs), 21 retrospective studies (4 with matched data), and five prospective studies. Eighteen were rated as providing high quality evidence.
Despite all meeting eligibility criteria, the articles varied considerably, in rigour and in study design and outcomes investigated. In addition to the nine outcomes under review (Table 2 and Box 2), studies examined various interventions (induction, augmentation, episiotomy, fetal monitoring, third stage management), pain management, duration of labour, birth positions, breastfeeding, transfer, maternal satisfaction and/or psychological well-being. Several investigated infants’ Apgar scores. Table 2 also includes a rating of research quality (risk of bias, summarised as high, moderate or low, Box 2).

Results and synthesis of selected outcomes

The results from meta-analyses of data from 25 studies across nine outcome variables are summarised in Tables 3 and 4, showing comparisons of planned hospital births with births planned at home and in birth centres. Forest plots from each meta-analysis are included in Supplementary Figures S1-S18, including separate results from AMUs and FMUs in birth centre analysis.

Tables 3 and 4 also report sensitivity analyses for selected outcomes repeating the meta-analysis using only the studies rated as high quality (i.e. > 75% on the ResQu Index). The description of infant mortality reports sensitivity analyses limited to studies which specifically excluded infants with known congenital abnormalities. We also repeated the meta-analyses of perinatal data from studies of planned home births, stratifying by parity where possible.

Infant outcomes

There was no significant difference in the odds of intrapartum stillbirth according to place of birth. This was true for meta-analyses combining data from studies of planned home birth (Table 3 and Fig S1) and births planned in birth centres (Table 3 and Fig S2). This finding did not change
when low and medium quality studies were removed from the analysis (Table 3). Limiting the analysis to studies where known congenital abnormalities were specifically excluded also yielded non-significant odds ratios (home births: OR=0.98 [95% CI: 0.66-1.46]; birth centres OR=0.65 [95% CI: 0.31-1.34]). Further analysis by parity indicated that there were no significant differences in the odds of stillbirth between births planned in hospitals and at home for either nulliparous and multiparous women (Table 3 and Fig S1a).

| TABLE 3 HERE |

There were no significant differences in the odds for early neonatal death (0-7 days) in relation to birth place, regardless of study quality (Fig S3 and Fig S4). Studies of planned home births that specifically excluded congenital abnormalities also showed a non-significant difference (OR=0.99 [95% CI: 0.77-1.26]). Studies of birth centres that excluded infants with congenital abnormalities had a non-significant OR of 0.99 [95% CI: 0.34-2.86]. Similarly, there were no significant differences in early neonatal death by parity between births planned at home and in hospital (Table 3 and Fig S3a).

Meta-analysis of four studies of planned home births identified significantly lower odds of NICU admission than for planned hospital births, as did the three high quality studies (Davis et al. 2011; de Jonge et al. 2015; Halfdansdottir et al. 2015). Babies of multiparous women had significantly lower odds of NICU admission if they planned a home birth rather than a hospital birth, although there was no significant difference by birth place among nulliparous women on this outcome (Figs S5 and S5a). Combining data from studies of planned birth centre births showed no significant difference in odds of NICU admission regardless of study quality (Table 3 and Fig S6).

**Maternal outcomes – mode of birth**
Women planning home births were nearly three times more likely to have a normal (non-instrumental) vaginal birth than women planning a hospital birth. The odds were higher when analysis was restricted to high quality studies (Table 4 and Fig S7) and to studies using a more specific definition of non-instrumental vaginal birth without induction of labour, epidural, spinal or general anaesthesia (Birthplace in England Collaborative Group et al. 2011; Burns et al. 2012; Homer et al. 2014) (OR=5.62 [95% CI: 1.30-24.24]). Women planning home births had significantly lower odds of either caesarean section or instrumental birth (approximately one third of those for women planning a hospital birth), regardless of study quality.

TABLE 4 HERE

Women planning a birth centre birth had nearly twice the odds of having normal vaginal births compared with women planning hospital births – with higher odds identified amongst higher quality studies (Table 4) and planned FMU births (Fig S8). Sensitivity analysis using the stricter definition found that women planning birth centre births had significantly higher odds of normal vaginal births without other interventions (n=3, OR=2.12 [95% CI: 1.54-2.92]). The odds of instrumental birth and caesarean section were also significantly lower for women planning to give birth in birth centres, regardless of type of birth centre or quality of the study (Fig S10 and S12).

Maternal outcomes - perineal status

Only two studies investigated the likelihood of an intact perineum amongst women planning home births, reporting significantly higher odds (Fig S13). The six studies investigating this variable in planned birth centre births found no significant difference in odds compared with planned hospital births, regardless of study quality (Table 4 and Fig S14).
The odds of severe perineal trauma were significantly lower amongst planned home births, regardless of study quality (Fig S15) and among higher-quality studies of births planned in birth centres (Table 4).

Maternal outcomes - PPH

Severe PPH (≥1000mL) was significantly less likely in planned home births than in planned hospital births (Fig S17). However, there was no significant difference in the odds identified in studies of planned birth centre births, regardless of the type of birth centre (Fig S18) or the rating of study quality (Table 4).

Discussion

Principal findings

This review examined whether there were significant differences between different planned birth places in critical maternal and perinatal outcomes, to help women make informed decisions about where to give birth. It is unique in including data from both birth centres and home births.

Limiting data to outcomes from low-risk pregnancies, we endeavoured to compare planned birth place cohorts across nine relevant outcomes. Combined maternal data from the selected studies indicated significantly lower odds of intervention and maternal morbidity, and significantly higher odds of normal vaginal births among planned home births compared to planned hospital births (Table 4). This is consistent with conclusions from other syntheses of research on planned home births (not all of which included comparative data) (Fullerton, Navarro & Young 2007; Leslie & Romano 2007; McIntyre 2012; Stotland & Declercq 2002; Zielinski, Ackerson & Kane Low 2015) and with Olsen’s early meta-analysis (1997). Further, women planning birth centre births had nearly twice the odds of a normal vaginal birth compared to women planning a hospital birth, with correspondingly lower rates of caesarean section or instrumental births. This is consistent with
findings from other reviews (Alliman & Phillippi 2016; Dixon et al. 2012; Hodnett, Downe & Walsh 2012; McIntyre 2012; Muthu & Fischbacher 2004). Our results found no significant difference in rates of severe perineal trauma or PPH between planned birth centre and hospital births.

While many authors have identified favourable maternal outcomes in planned birth centre and home births, including outcomes not addressed in this review, results regarding infant outcomes from different places of birth are more controversial. Our meta-analysis found no significant difference between the cohorts in the odds of stillbirth or early neonatal death (Table 3), albeit by combining several studies with limited statistical power to detect differences in such rare outcomes. This was consistent for studies of births planned in birth centres and at home, regardless of study quality. Moreover, the odds of perinatal mortality did not differ between births planned in hospital and at home, among both nulliparous and multiparous women. The absolute numbers of adverse events were still very small (Olsen & Clausen 2012). There were significantly lower odds of admission to NICU for babies of women planning a home birth than those of women planning hospital births.

Limitations

Given different countries of origin, the selected studies varied considerably in context: service provision, setting, models of care and the overall integration between maternity services. Thus, generalisation of findings to high-income countries with different healthcare systems requires caution. There was diversity too in the quality of the included studies, although we attempted to reduce its impact through strict eligibility criteria and appraisal with the ResQu Index. Studies explored a wide range of outcomes; even common outcomes were sometimes defined differently, limiting the extent to which we could extract comparable data. Thus not all studies addressing a given outcomes contributed data to its relevant meta-analyses.
Limiting eligibility to publication in English language peer-reviewed journals may have resulted in some publication bias across studies, overlooking studies from some regions. Publication bias may have also resulted in the inclusion of studies that only reported significant differences between cohorts. However, given the controversial nature of this topic and the strong perspectives of different provider groups in some regions, it is likely that good quality studies on perinatal and maternal outcomes would usually be published find an outlet. Further, for some outcomes such as mortality, a non-significant difference between places of birth is as news noteworthy as one that is statistically significant.

We only conducted a few meta-analyses in terms of parity, focussing on adverse perinatal outcomes from planned home births. Although we recognise that parity is an important determinant of maternal and perinatal outcomes, many studies did not present data by parity. Further, by focusing specifically on birth setting, we did not explore the impact of provider type or model of care.

Most research into place of birth is observational. Our quality appraisal process, eligibility criteria and data extraction endeavoured to minimise bias between individual studies in design, analysis and reporting. However, there may have been systematic differences in confounders that could be overcome through randomisation. The rarity of perinatal mortality in high-income countries necessitates combining studies to provide sufficiently large home birth or birth centre cohorts to show meaningful results.

Another proposed systematic review and meta-analysis (Hutton et al. 2014) is in progress. It will focus on studies of home birth outcomes that stratify by parity and those in countries where home birth is well integrated with other maternity services.

**Heterogeneity**
Not surprisingly, several meta-analyses showed high heterogeneity ($I^2$) scores (Figures S1-S18), especially for mode of birth. These scores largely reflect the variation in sample size and in the outcomes of the individual studies and are consistent with the conclusions of other reviews that have highlighted the disparities between selected observational studies. The measures generated by the software may overlook other aspects of heterogeneity in studies, such as unmeasured differences in staffing or resources between birth settings or in underlying characteristics of the women in different cohorts.

**Risk status**

We closely analysed the studies’ definitions ‘low-risk’, rather than comparing them with a strict definition determined *a priori*. Most studies gave detailed criteria, including at minimum gestational age, fetal presentation, and singleton pregnancy. The descriptions of exclusion criteria varied from vaguely-defined ‘pre-existing medical conditions’ or ‘obstetric complications’, through to comprehensive lists of factors which contribute significantly to risk status. Even where they demonstrated similar levels of obstetric risk, several studies identified marked disparity in the demographic characteristics between cohorts. Most studies adjusted reported odds ratios to take account of some if not all of these demographic differences; some discussed the impact of less measurable distinctions between their cohorts (e.g. motivation, attitudes).

**Quality appraisal**

This paper is unique in using the ResQu Index, an innovative instrument to appraise research specifically on place of birth (Vedam, Rossiter, et al. 2017). Although the development of the Index included expert validation and extensive pilot-testing, this is the first known application of the tool in a systematic review. Only ten included studies scored as moderate or low in quality. This does not demonstrate that the Index is undiscriminating; rather it reflects that review inclusion criteria
were strict and addressed similar considerations as the ResQu Index itself (e.g. adherence to intention-to-treat analysis or exclusion of non-comparable cohorts).

Findings from the sensitivity analyses (Tables 3 and 4) indicate that the overall odds ratios rarely changed substantially by ruling out weaker studies, which typically had smaller sample sizes. In one meta-analysis of perineal trauma among planned birth centre births, data limited to higher quality studies generated a statistically significant difference from planned hospital births whereas analysis of all studies yielded a non-significant difference.

**Conclusions**

By comparing and synthesising results from three distinct birth settings, this review offers valuable evidence to inform decisions about birth place. The results demonstrate that, amongst carefully selected studies of women with low-risk pregnancies in high-income countries, planned place of birth appears to have little significant impact on adverse perinatal outcomes. Moreover, women who planned to give birth in a birth centre or at home had significantly lower odds for intervention and severe morbidity in labour and birth.

These findings have important implications for healthcare costs and services. They support the expansion of birth centres and home birth options, and the systems to support them, including professional guidelines and education. The results also have ramifications for information provided to pregnant women and their families, as a means to enhance their choice and autonomy about birthplace options. They help extend existing knowledge about the risks and potential outcomes from different places and birth, and the circumstances necessary to optimise the safety and well-being of mothers and newborns.

### Table 1. Inclusion and exclusion criteria for articles in systematic review

<table>
<thead>
<tr>
<th>Inclusion criteria</th>
<th>Exclusion examples</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Participants</strong></td>
<td></td>
</tr>
</tbody>
</table>
| Healthy women with low-risk pregnancies, assessed by the researchers using clear consistent criteria | • Non-human participants  
• Women with known antenatal risk factors e.g. twins, non-vertex presentation, previous caesarean section, pre-term labour, elective caesarean section, gestational diabetes, hypertension  
• Risk self-rated by study participants  
• Risk factors not comparable in all study cohorts |
| Women giving birth in a high-income country | • Women in low- or medium-income countries  
• Women in two or more high-income countries, where outcomes may be affected by variation between jurisdictions rather than place of birth |
| **Intervention**    |                    |
| Intended place of birth, determined at or close to the onset of labour | • Model of care or provider type rather than birth place  
• Actual place of birth, regardless of intention  
• Intended birth place determined at booking, not close to onset of labour  
• Cohorts including births without skilled attendants  
• Cohorts including unplanned home births  
• Studies where intended place of birth is a comparator rather than the independent variable  
• Comparison of specific antenatal, intrapartum or postnatal interventions or management approaches |
| **Comparison**      |                    |
| Comparison of two or more intended birth settings – home birth, birth in hospital obstetric unit or birth centre (including, where relevant, free-standing and alongside midwifery units) | • Studies of outcomes in one birth setting i.e. just home births or birth centres, without comparison cohort  
• Studies of modified rooms within hospital obstetric unit  
• (Meta-analysis excluded studies comparing birth centres with home births as the meta-analysis which uses hospital births as referent.) |

|                          | Neonatal intensive care |
|                          | Special care nursery |

CV1 = Childbirth Variable 1

Child birth OR Childbirth OR Maternity OR Midwife OR Obstetric

CV2 = Childbirth Variable 2

Perinatal OR Neonatal OR Maternal OR Newborn OR Pregnancy OR Obstetric OR F(o)etal OR Infant

1. Although model of care was not the focus of this review, we used it as a search term as some studies of alternate models of care also report outcomes by place of birth.

2. Because the review focuses on comparisons between different birth places, it was not necessary to use search terms related only to hospital-based births (delivery suite, labour ward, obstetric unit etc). Searching using terms related to home births and birth centres (as above) identified studies comparing these with hospital-based births, thus reducing the search time involved.

Box 2: Definition of data terms
Birth Place (= Birth Setting = Place of Birth)

Birth centre: a separate area designated to provide midwife-led primary-level care in a home-like setting with no routine involvement of medical staff. Birth centres may be located as part of a hospital (Alongside Midwifery Unit – AMU) or a Freestanding Midwifery Unit (FMU). Access to specialist obstetric, anaesthetic or paediatric consultation requires transfer to a hospital obstetric unit. Birth centres may be publicly or privately funded.

Planned home birth: where a woman intends to give birth outside a formal health facility, usually in her home, and plans to receive care from one or more qualified birth attendants (midwife or doctor recognised in their country as competent to provide care). Home birth may be funded publicly or privately.

Hospital birth: births planned to take place in a hospital obstetric unit (OU) which is staffed by qualified midwives, nurses and doctors. Hospitals provide access to anaesthetic, surgical and neonatal facilities and may be public or privately-funded.

**********

High-income country: as defined by the World Bank for the 2016 fiscal year (World Bank 2016).

Intended place of birth: recorded as close as possible to the onset of care in labour and preserving integrity of cohorts by taking account of intrapartum or postpartum transfers from home or birth centre to hospital. We approximate intention-to-treat by including the outcomes of the place of birth determined at (or close to) the start of labour.

Low-risk pregnancy: definitions may vary by country or by study. However, it is critical that studies specify the criteria utilised, the source of their definition and apply the same criteria to different birth place cohorts to maximise comparability. Ideally studies use recognised guidelines for determining low obstetric risk (e.g. NICE guidelines). In addition to specifying term, vertex, singleton pregnancies, studies should also indicate clearly what other maternal factors are eliminated from the dataset, e.g. hypertension, pre-existing medical conditions. For simplicity, this paper refers to ‘low-risk pregnancies’ and acknowledges variation in definitions in selected studies.

Mode of birth: Normal vaginal birth, instrumental birth (forceps or vacuum extraction) or non-elective caesarean section. Elective caesarean sections are correctly excluded from samples of women with low-risk pregnancies.

NICU admission: admission of newborn after birth to a neonatal intensive care unit

Normal vaginal birth is defined variously by study authors. The meta-analysis groups results for births other than caesarean sections or instrumental birth. However, we also conducted sensitivity analyses based on a more rigorous definition i.e. births other than caesarean sections or instrumental birth, specifically stating there was no induction of labour, epidural or spinal analgesia or episiotomy; vertex presentation.

Outcomes: measurable results for mother and/or infant with an emphasis on items related to safety as commonly defined by clinical studies. We focused on outcomes resulting from care in labour and birth, rather than the processes of that care, and did not include data on interventions such as induction, analgesia, anaesthesia, and episiotomy. Similarly we do not
review data about Apgar scores because of the subjective nature of this measure and the variety of thresholds reported in the literature.

Our analysis principally focuses on nine outcomes: perinatal mortality (intrapartum stillbirth and early neonatal mortality 0-7 days), NICU admission, mode of birth (normal vaginal birth, instrumental birth, caesarean section), perineal status (intact perineum and severe perineal trauma) and post-partum haemorrhage >1000mL. Many studies investigated additional outcomes (see Table S3).

**Perinatal mortality:** data on intrapartum death of a fetus known to be alive at the onset of labour (stillbirth) and early neonatal death (0-7 days). Sensitivity analyses group data from studies specifically excluding deaths resulting from known congenital abnormalities.

**Perineal status:** This review reports results on either intact perineum (no lacerations and no episiotomy) or severe perineal trauma (third or fourth degree lacerations).

**Postpartum haemorrhage (PPH):** blood loss of greater than 1000mL.

**Research quality:** refers to a study's score on the ResQu Index (Vedam et al. 2017)

1. High quality evidence – 75% or above
2. Moderate – 65-74%
3. Low – below 65%

**Spontaneous vaginal birth:** see Normal vaginal birth.

**IDENTIFICATION**

- Records identified through electronic database searches: 4059
- Records identified via other sources: 8

**SCREENING**

- Total records identified: 4064
- Remaining records screened by title: 3106
- Remaining records screened by abstract: 748

**ELIGIBILITY**

- Remaining records screened by full text for eligibility in Systematic Review: 101
- Remaining records screened by full text for eligibility for SR and meta-analysis: 86

**Papers included in systematic review: 28**

**Papers included in meta-analysis (NB different definitions etc): 25**
