17 **Abstract**

18 The feasibility of a novel bioflocculant (GemFloc™) for membrane fouling mitigation
19 in membrane bioreactor (MBR) was investigated during real municipal wastewater
20 treatment. When compared to the conventional MBR (CMBR), suspended sludge in the
21 MBR with GemFloc™ (G-MBR) showed less soluble microbial products (SMP), higher
22 ratios of proteins to polysaccharides in SMP (SMP_p/SMP_c) and loosely bound extracellular
23 polymeric substances (LB-EPS). Adding GemFloc™ also enlarged floc size ($> 200 \mu m$),
24 and increased tightly bound EPS levels, zeta potential and relative hydrophobicity of sludge
25 flocs, further reduced cake layer and pore blocking resistances. Moreover, more diverse
26 microbial community and enrichment of fouling reduction microbes such as *Arenimonas*

27 and *Flaviumibacter* were observed in the G-MBR, together with less abundant microbes
28 (e.g. *Sphaerotilus* and *Povalibacter*) which could aggravate membrane fouling. Therefore,
29 GemFloc™ has high capability in improving sludge characteristics, mitigating membrane
30 fouling and increasing diversity of special functional bacterial community in MBR.

33 treatment; Membrane fouling control; Microbial community

34

35 1. Introduction

36 Membrane bioreactor (MBR) has been popularly used for treatment and reclamation of
37 various types of wastewater (e.g. municipal wastewater, industrial wastewater, domestic
38 wastewater) since it possesses compact nature (less footprint), ensures high-quality effluent,
39 has capability in resisting high organic loading, generates largely disinfected effluent, and
40 limits sludge generation (Zhang et al., 2019). However, membrane fouling is the major
41 obstacle inhibiting wide application of MBR. Therefore, it is necessary to develop effective
42 strategy to alleviate membrane fouling.

43 Coagulation/flocculation as an effective treatment approach with various types of
44 flocculants has been employed for membrane fouling mitigation in MBR. Inorganic
45 flocculants, especially ferric based flocculants (e.g. $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$, $\text{Fe}_2(\text{SO}_4)_3 \cdot 5\text{H}_2\text{O}$,
46 FeClSO_4 , etc.), could enhance sludge filterability, reduce reversible fouling, and ameliorate
47 irreversible fouling by removing soluble microbial products (SMP), leading to greater
48 transmembrane pressure (TMP) decline (Gkotsis et al., 2017). Huang et al. (2019) explored

49 the feasibility of ferric hydroxide in membrane fouling mitigation in MBR during
50 pharmaceutical wastewater treatment. After adding ferric hydroxide into MBR (Fe-MBR),
51 the amount of larger biomass flocs increased through neutralizing negatively surface charge
52 of activated sludge compared to a control MBR (co-MBR). The increase in bacterial
53 activity and significant decline in relative abundance of bacteria contributing to biofilm
54 formation (e.g. *α-proteobacteria*, *β-proteobacteria*, *Flavobacteriia*) reduced dissolved
55 organic matters (DOMs) in SMP (e.g. dissolved organic carbon, carbohydrate, low
56 molecular weight compounds and biopolymer). These effects effectively mitigated
57 membrane fouling in the Fe-MBR (about 35% longer operational duration compared to the
58 Co-MBR). On the other hand, organic flocculants (e.g. biopolymers, cationic polymers,
59 etc.) can not only prolong filtration cycles, but also reduce inorganic elements (e.g. silicon,
60 calcium, magnesium, aluminium, and iron) as well as concentrations of SMP, extracellular
61 polymeric substances (EPS) and colloidal total organic carbon. These flocculants also
62 enlarged mean floc size, which further increased impact resistance and enhanced floc's
63 adaptive capacity to changing environment, resulting in less SMP release (Alkmim et al.,
64 2015; Zhou et al., 2017a).

65 Nevertheless, inorganic and organic flocculants can exert adverse impact on
66 environment and human health, and may generate 'secondary pollutants' (e.g. metals, toxic
67 sludge, acrylamide oligomers, etc.) during wastewater reclamation and reuse processes
68 (Mateus et al., 2017). Therefore, bioflocculants or natural flocculants have been developed
69 and used for fouling alleviation due to less ecological and health impact. Tan et al. (2017)
70 employed salt-tolerant *Arthrobacter* as a kind of bioflocculants and slower membrane
71 fouling development was observed in MBR when treating saline wastewater. The

72 bioflocculation by *Arthrobacter* not only facilitated the reduction of fouling-related
73 components (e.g. EPS in sludge, SMP in supernatant solution), but also decreased the
74 humic acid-like, fulvic acid-like and aromatic proteins components (large biomolecules).
75 Modified starches (e.g. MGMS, CGMS) could remarkably reduce gel and cake resistances
76 as well as concentrations of macromolecules with molecular weight (MW) ≥ 100 kDa in
77 supernatant of MBR. Compared with MGMS, the addition of CGMS in MBR (CGMS-
78 MBR) generated larger-size sludge flocs with lower fractal dimension, thus increasing
79 porosity of fouling layer. It also prompted detachment of flocs from membrane surface,
80 leading to lower fouling rate in the CGMS-MBR (Ji et al., 2015).

81 Our previous studies used a new green bioflocculant in MBR for synthetic domestic
82 wastewater treatment. Compared to the conventional MBR, the bioflocculant could reduce
83 energy consumption due to less backwash frequency, significantly alleviate membrane
84 fouling (TMP increase of 2.5 kPa during 70 days of operation), improve sludge properties
85 (e.g. less SMP, larger floc size, higher zeta potential, higher relative hydrophobicity) as
86 well as limit cake layer formation and pore blocking (Deng et al., 2015; Ngo and Guo et al.,
87 2009). However, the application of bioflocculant in real wastewater treatment and the
88 resulting changes in microbial community in activated sludge have yet to be explored.
89 Hence, in this study, the performance of two lab-scale MBRs, one with the patented
90 bioflocculant (GemFloc™) developed at University of Technology Sydney and the other
91 without bioflocculant were compared for real municipal wastewater treatment during long-
92 term operation. More specifically, membrane fouling behaviors (TMP and fouling
93 resistance) were evaluated together with sludge characteristics (including mixed liquor

94 suspended solids (MLSS), mixed liquor volatile suspended solids (MLVSS), zeta potential,
95 relative hydrophobicity (RH), particle size distribution (PSD), EPS and SMP
96 compositions). Given the important role of bacterial population in determining sludge
97 characteristics and membrane fouling behaviors, this paper also analyzed microbial
98 community structure in both MBRs.

99

100 **2. Materials and methods**

101 **2.1. Real wastewater**

102 Real municipal wastewater taken from a local wastewater treatment plant (WWTP),
103 Xian, China was employed as the feed for both MBRs in this study. The real wastewater
104 contains COD_{Cr} of 400-560 mg/L, BOD₅ of 198-236 mg/L, NH₄-N of 26.8-37.2 mg/L, total
105 nitrogen (TN) of 40.2-56.1 mg/L and total phosphorus (TP) of 8.63-11.91 mg/L with pH of
106 7.52 ± 0.36 . pH of MBRs was adjusted by NaHCO₃ or H₂SO₄ to a constant value of 7.

107

108 **2.2. Experimental set-up and operating conditions**

109 Two lab-scale submerged MBRs with same effective working volume of 5 L, including
110 MBR with GemFloc™ addition (G-MBR) and conventional MBR (CMBR), were operated
111 in parallel. The submerged hollow fiber membrane module in MBR was made of
112 polyvinylidene fluoride (PVDF) membrane fibers (Tianjin Motimo Membrane Technology
113 Co., Ltd.) with pore size of 0.03 μm and an effective surface area of 0.12 m². Activated
114 sludge in both MBRs was collected from the WWTP and was acclimatized for more than
115 two weeks using real wastewater before starting. Initial mixed liquor suspended sludge
116 concentration was adjusted to around 5.0 g/L in both MBRs. During the experimental

117 period, sludge was not discharged to obtain infinite sludge retention time (SRT).
118 GemFloc™ dosage in the G-MBR was 0.5 g/d. The suction pump was employed to
119 withdraw permeate from the membrane module at a constant filtration flux of 8 L/m²·h.
120 Thus the hydraulic retention time (HRT) amounted to 5.21 h. An air diffuser placed below
121 the membrane module was employed to supply aeration from an air compressor. The air
122 flow rate was kept at 2.5 L/min. Periodical backwash at two times per day was adopted to
123 physically clean membrane. When TMP reached above 35.0 kPa, off-line chemical
124 membrane cleaning was conducted by immersing the membrane module in 0.8% (w/w)
125 hydrochloric acid for 8 h, followed by 0.9% (w/w) sodium hypochlorite for 8 h and finally
126 0.4% (w/w) sodium hydroxide for 8 h.

127

128 **2.3. Analysis methods**

129 Measurements of MLSS and MLVSS were conducted according to the standard
130 methods (APHA et al., 1998). The standard methods (APHA et al., 1998) were also
131 adopted for determination of chemical oxygen demand (COD), ammonia (NH₄-N), nitrite
132 (NO₂-N), nitrate (NO₃-N) and phosphorus (PO₄-P) concentrations of influent and effluent
133 by employing a HACH DR6000 UV VIS spectrophotometer (HACH Co., USA). Sludge
134 volume index (SVI) of suspended sludge was gauged in a 1000 mL graduated cylinder.
135 Sludge samples were centrifuged at 3000 rpm for 30 min to obtain supernatant, which was
136 centrifuged again and further filtered through 0.45 µm syringe filter. The final solution was
137 collected as soluble microbial products (SMP) (Deng et al., 2015). According to Chen et al.
138 (2017a), the sludge pellets in the centrifuge tube were re-suspended in 0.05% NaCl

139 solution, followed by being sonicated at 20 kHz for 2 min, shaken at 150 rpm for 10 min,
140 sonicated again, and centrifuged at 8,000 g for 10 min to get the supernatant for loosely
141 bound extracellular polymeric substances (LB-EPS). Extraction of supernatant for tightly
142 bound extracellular polymeric substances (TB-EPS) was carried out by re-suspending
143 sludge pellet left in the centrifuge tube in 0.05% NaCl solution, which was further
144 sonicated at 20 kHz for 3 min, heated at 60 °C for 30 min and centrifuged at 12,000 g for 20
145 min to collect the supernatant. The aforementioned supernatants were filtered through 0.45
146 µm syringe filter to obtain LB-EPS and TB-EPS. Proteins (LB-EPS_P, TB-EPS_P and SMP_P)
147 and polysaccharides (LB-EPS_C, TB-EPS_C and SMP_C) in extracted samples were analysed
148 by modified Lowery method (Sigma, Australia) and Anthrone-sulphuric acid method,
149 respectively. Concentrations of proteins and polysaccharides were finally determined by the
150 above-mentioned HACH spectrophotometer. A zeta potential meter (Zetasizer Nano ZS,
151 Malvern Instrument, UK) was used for determining zeta potential of mixed liquor. The
152 relative hydrophobicity (RH) of sludge flocs was analysed based on the protocol proposed
153 by one of our previous studies (Deng et al., 2015). The determination of particle size
154 distribution of sludge flocs was conducted using a laser granulometer (Mastersizer 2000,
155 Malvern Instruments, UK).

156 After terminating the experiment at TMP above 35 kPa, resistance-in-series model and
157 Darcy's equations were applied to determine membrane filtration characteristics (Choo and
158 Lee, 1996):

$$159 \quad J = \Delta P / \mu R_T \quad (1)$$

$$160 \quad R_T = R_M + R_C + R_P \quad (2)$$

161 where J is the permeate flux, ΔP is the TMP, μ is the viscosity of the permeate, R_T is total
162 resistance, R_M is the intrinsic membrane resistance, R_C is the cake resistance, and R_p is the
163 pore blocking resistance.

164 The bacterial community structure of suspended sludge samples were analysed by
165 Sangon Biotech in China using high-throughput sequencing.

166

167 **3. Results and discussion**

168 **3.1. Organic and nutrient removals**

169 Both of the G-MBR and the CMBR showed good COD removal of $96.25 \pm 7.81\%$ and
170 $90.36 \pm 8.36\%$, respectively, implying slightly enhanced organic matter removal by
171 application of the biofloculant. Although small difference in $\text{NH}_4\text{-N}$ removal was observed
172 between the G-MBR ($90.67 \pm 6.82\%$) and the CMBR ($85.72 \pm 8.45\%$), the G-MBR
173 demonstrated greater TN removal ($80.36 \pm 5.12\%$) compared to the CMBR ($37.75 \pm$
174 7.24%). It was ascribed to that the retention of nitrifying bacteria by the membrane in both
175 MBRs led to high degree of biological nitrification. When compared with the CMBR, the
176 presence of larger flocs in the G-MBR might facilitate the formation of anoxic/anaerobic
177 microenvironment at the inner layer of the flocs. Better TN removal in the G-MBR could
178 be due to the occurrence of oxygen gradient inside these larger flocs (see Section 3.2)
179 despite of high DO levels (5.0-7.0 mg/L). The addition of GemFloc™ could also improve
180 the accumulation of phosphorus accumulating organisms (PAOs) and biomass metabolism,
181 which, in turn facilitated enhanced biological phosphorus removal, achieving better $\text{PO}_4\text{-P}$
182 removal in the G-MBR ($93.61 \pm 7.58\%$) compared to that for the CMBR ($59.33 \pm 8.96\%$).

183 More detailed analyses regarding microbial community structure contributing to organic
184 and nutrient removals are presented in Section 3.4.

185

186 **3.2. Membrane fouling behaviors**

187 During the entire study period, TMP of the CMBR exhibited a gradual increment from
188 2.70 to 10.35 kPa within the first 21 days of operation followed by a sharp jump, reaching
189 36.20 kPa on day 30 (Fig. 1). Compared to the CMBR, the G-MBR presented a slower
190 TMP increase from 2.57 to 15.36 kPa before day 51. Subsequently, a remarkable TMP rise
191 was observed and chemical cleaning was implemented until day 58 as TMP exceeded 35
192 kPa (36.68 kPa). It could be inferred that the fouling rate for the CMBR (1.11 kPa/d) was
193 almost two times higher than that for the G-MBR at 0.59 kPa/d. Hence, GemFloc™
194 addition significantly slowed down membrane fouling development, enhanced membrane
195 permeability and extended the operational duration of MBR.

196 **Fig. 1.**

197

198 At the end of experiment, fouling resistance distribution was obtained for both the G-
199 MBR and the CMBR (Table 1). The CMBR exhibited considerably higher total fouling
200 resistance (R_T) than the G-MBR (6.13×10^{12} and $3.73 \times 10^{12} \text{ m}^{-1}$, respectively). GemFloc™
201 addition significantly reduced cake layer resistance (R_C) in the G-MBR by 46.78%,
202 obtaining $2.40 \times 10^{12} \text{ m}^{-1}$. R_C of both MBRs made a great contribution to R_T , accounting for
203 64.34% and 73.57% of R_T for the G-MBR and the CMBR, respectively. Pore blocking
204 resistance (R_P) in the G-MBR ($0.17 \times 10^{12} \text{ m}^{-1}$) was about one third of that for the CMBR

205 $(0.46 \times 10^{12} \text{ m}^{-1})$. Thus GemFloc™ could effectively retard cake layer formation and pore
206 blocking, thus alleviating membrane fouling.

207 **Table 1.**

208

209 **3.3. Sludge properties**

210 **3.3.1. MLSS concentration**

211 The G-MBR and CMBR possessed initial MLSS concentrations of 4.98 g/L and 5.06
212 g/L, respectively. Since there was no sludge withdrawal during the experiment, continuous
213 growth of suspended biomass occurred, finally reaching 11.62 g/L in the G-MBR on day 58
214 and 11.05 g/L in the CMBR on day 30, which indicated that lower biomass growth rate
215 ($\Delta\text{MLSS}/\Delta t$) was obtained due to GemFloc™ addition (0.11 g/L·d) compared to that for the
216 CMBR (0.19 g/L·d). The lower SVI of 71.88-129.89 mL/g for the G-MBR (91.54-151.82
217 mL/g for the CMBR) also implied the denser and heavier settled sludge and better
218 settleability of sludge. MLVSS concentrations ranged from 3.39 to 10.00 g/L and from 3.40
219 to 8.21 g/L in the G-MBR and CMBR, respectively. The obtained higher MLVSS/MLSS
220 ratio in the G-MBR in the range of 0.68-0.86 than that in the CMBR (0.67-0.74) might be
221 owing to the presence of GemFloc™ increased fraction of organic content and reduced
222 biomass mineralization (Krzeminski et al., 2012).

223

224 **3.3.2. Particle size distribution of biomass flocs**

225 In the CMBR, sludge flocs showed a narrow particle size distribution from 0.4 to 600
226 μm . The sludge flocs with size less than 150 μm and larger than 200 μm accounted for

227 about 64% and 21% of total sludge volume, respectively (Fig. 2). During the first 15-day
228 operation, particle size distribution of sludge flocs in the G-MBR was in a wide range of
229 0.4-1300 μm . Small flocs ($< 150 \mu\text{m}$) and larger flocs ($> 200 \mu\text{m}$) took 57% and 26% of
230 total sludge volume, respectively. After that, sludge flocs in the G-MBR shifted towards a
231 broader particle size distribution with median particle size larger than 200 μm (50% of total
232 sludge volume) and smaller floc size $< 150 \mu\text{m}$ (38% of total sludge volume). From day 50,
233 the proportion of larger flocs declined but that of small flocs increased, as demonstrated by
234 47% for flocs smaller than 150 μm and 39% for flocs larger 200 μm . Additionally, the floc
235 size range was narrowed to 0.4-800 μm . The decrease in the proportions of large flocs but
236 increase in percentages of small flocs in total sludge volume after 50 days was almost
237 consistent with the trend of TMP development (TMP jump) in the G-MBR. It indicated that
238 serious membrane fouling after 50 days could be partially explained by the increased
239 amounts of small flocs. Nevertheless, the fraction of larger flocs was still higher in the G-
240 MBR than those for the CMBR throughout the whole experiment.

241 **Fig. 2.**

242

243 As particle size of sludge flocs were at least ten times than that of the membrane pore
244 size, the biomass floc size in this study might not be considered as the key factor
245 contributing to pore blocking. Backtransport velocity of sludge flocs with smaller size was
246 smaller due to lower physical forces on the particles (i.e. inertial lift), which increased
247 amount of small flocs in the cake. This further reduced permeability and void fraction of
248 cake layer (Ma et al., 2013). Thus greater proportion of smaller flocs in the CMBR
249 accounted for the increased R_C . On the other hand, GemFloc™ showed its positive and

250 long-term effects on flocculation ability and aggregation of sludge flocs, which favored the
251 formation of larger biomass flocs, leading to formation of more porous and higher
252 permeable cake layer on membrane surface (Park et al., 2006). Consequently, R_C was lower
253 in the G-MBR than that in the CMBR.

254 Compared to those in the CMBR (zeta potential of -18.6 mV – -15.1 mV, relative
255 hydrophobicity (RH) of 32.36% – 42.76%), GemFloc™ addition increased zeta potential ($-$
256 11.1 mV – -7.25 mV) by neutralizing or reducing negative surface charge of sludge flocs
257 and enhanced sludge hydrophobicity by increasing RH (64.13% – 79.33%) of sludge flocs
258 in the G-MBR. These effects increased flocculation ability of sludge flocs, which was
259 associated with the enlarged floc size of suspended sludge in the G-MBR.

260

261 3.3.3. EPS and SMP compositions of suspended sludge

262 At relatively low TMP (< 16 kPa), the CMBR possessed higher levels of total SMP
263 and polysaccharides in SMP (SMP_C) (20.47 - 55.86 and 9.06 - 30.18 mg/L, respectively)
264 compared to the G-MBR (14.82 - 44.09 and 5.33 - 17.36 mg/L, respectively), corresponding
265 to lower ratios of proteins to polysaccharides (SMP_P/SMP_C) (0.76 - 1.59 in the CMBR and
266 1.54 - 2.09 in the G-MBR) (Table 2). When membrane fouling became more serious (TMP
267 16 - 37 kPa), total SMP remarkably increased in the CMBR (61.18 - 95.85 mg/L).
268 Additionally, SMP_C showed a notable ascending trend, reaching 32.39 - 53.67 mg/L. On the
269 other hand, contents of SMP and SMP_C in the G-MBR were lower at 53.12 - 62.98 and
270 23.76 - 29.26 mg/L, respectively. Significantly declined SMP_P/SMP_C ratio was detected for
271 the CMBR (0.79 - 0.89) when compared with that for the G-MBR (1.15 - 1.24). Greater levels

272 of SMP aggravated membrane fouling in the CMBR by encouraging membrane pore
273 blocking, formation of gel layer with considerably high specific filtration resistance as well
274 as penetration into spaces between particles and pores in cake layer. Moreover, as
275 polysaccharides contribute to membrane fouling development (especially irreversible
276 fouling) and gel layer formation on membrane surface (Deng et al., 2016), more serious
277 membrane fouling, greater R_p and R_c in the CMBR could be partially ascribed to higher
278 SMP levels and lower SMP_p/SMP_c ratio.

279 **Table 2.**

280

281 Compared to the G-MBR (LB-EPS of 43.80-123.72 mg/L and $LB-EPS_p/LB-EPS_c$ of
282 1.56-3.14 mg/L, respectively), higher concentrations of LB-EPS and lower ratio of proteins
283 to polysaccharides in LB-EPS ($LB-EPS_p/LB-EPS_c$) were detected in the CMBR at different
284 TMP ranges, corresponding to 62.69-180.84 and 0.89-2.06 mg/L, respectively. LB-EPS has
285 highly hydrated matrix, possessing a dispersible and loose slime layer without an obvious
286 edge. Thus the presence of LB-EPS at greater levels induced poor attachment between cells
287 and floc structure, caused the production of highly porous sludge flocs at low density, and
288 deteriorated sludge bioflocculation. This could give rise to poorer settleability of sludge
289 flocs (higher SVI values), larger amount of fine particles and serious membrane fouling in
290 the CMBR (Li and Yang, 2007). Hence higher R_c and R_p in the CMBR were also ascribed
291 to higher LB-EPS levels.

292 In the G-MBR, the greater $LB-EPS_p/LB-EPS_c$ increased zeta potential and RH of
293 sludge flocs as proteins provide the amino groups with positive charge and amino acids
294 with hydrophobic side group, resulting in better flocculation ability of flocs and further

295 favored formation of bigger and more permeable flocs (Zhang et al., 2016). TB-EPS which
296 attaches to peripheral capsules of cell surface favors the aggregation of cells in clusters.
297 The increased TB-EPS levels of activated sludge helped agglomeration of sludge flocs by
298 GemFloc™ addition (85.37-121.93 mg/L for the G-MBR, 67.84-83.61 mg/L for the
299 CMBR), which enlarged flocs in the G-MBR (Chen et al., 2017b). Furthermore, levels of
300 proteins as major components of TB-EPS (TB-EPS_P) were higher in suspended sludge of
301 the G-MBR (54.11-78.26 mg/L) than those for the CMBR (45.36-59.51 mg/L). Proteins
302 could keep bacterial cells together and maintain cell cohesion by forming an active gel-like
303 matrix (Dogsa et al., 2005). Thus more TB-EPS_P in activated sludge also facilitated the
304 formation of larger flocs due to addition of GemFloc™. In the G-MBR, higher LB-
305 EPS_P/LB-EPS_C ratio and TB-EPS_P levels were responsible for the formation of larger flocs.

306

307 **3.4. Microbial community structure at genus level**

308 **3.4.1. Microbial community structure contributing to organic and nutrient removals**

309 Higher proportion of *Phaeodactylibacter* was found in the G-MBR (1.27-3.01%) than
310 that in the CMBR (< 1.21%), which might help to improve organic matter removal by
311 application of GemFloc™ throughout the entire experimental period (Xu et al., 2018).
312 During TMP development in the range of 10-16 kPa, both of the G-MBR and CMBR
313 possessed high relative abundance of nitrifying bacteria, including *Nitrosomonas* (10.88%
314 and 9.54%, respectively) and *Nitrospira* (5.19% and 4.12%, respectively). More abundant
315 denitrifying bacteria (7.92% for *Deffluviimonas*, 4.98% for *Pseudolabrys*) and PAOs (1.46%
316 for *Gemmatimonas*) were found due to GemFloc™ addition compared to that in the CMBR

317 (3.52%, 1.32%, and 0.76%, respectively). When TMP reached above 35 kPa, greater
318 abundance of nitrifying bacteria and PAOs were also found in the G-MBR compared to the
319 CMBR (8.36% vs 4.88% for *Nitrosomonas*, 3.27% vs 2.36% for *Nitrospira*, 3.55% vs
320 0.97% for *Gemmatimonas*). The declined ratios of *Nitrosomonas* and *Nitrospira* might be
321 mainly ascribed to that the increase in diversity of microbial population decreased the
322 proportion of nitrifying bacteria in total microbial population. These results could explain
323 better nitrogen and phosphorus removal achieved by GemFloc™ addition (Miao et al.,
324 2015; Zhang et al., 2003; Zhou et al., 2017b).

325

326 3.4.2. Microbial community structure contributing to membrane fouling

327 Microbial community structure in the CMBR and G-MBR regarding the
328 microorganisms associated with membrane fouling and sludge characteristics are displayed
329 in Figs. 3 and 4. In the CMBR, majority of microbial population was associated with
330 serious membrane fouling and poor sludge properties. At low TMP (10-16 kPa), great
331 abundance of *Haliscomenobacter* (as one kind of filamentous bacteria, 7.50%) and
332 *Hyphomicrobium* (8.56%) deteriorated sludge settleability and compaction, which might be
333 responsible for the increase of SVI (Gu et al., 2018; Layton et al., 2000). The abundant of
334 another filamentous microbe, namely *Thiothrix* (8.18%), indicated the generation of
335 extracellular polymers (e.g. LB-EPS) and further aggravated membrane fouling (Gao et al.,
336 2014). More LB-EPS_C and more serious membrane fouling could be associated with high
337 abundance of *Bradyrhizobium* (3.62%) which could secrete extracellular polysaccharides
338 (Friha et al., 2014). *Novosphingobium* is normally found in biocake or biofilm and

339 *Chryseolinea* can induce membrane fouling by fermentation of polysaccharides (Matar et
340 al., 2017; Xu et al., 2018). Hence the enrichment of *Novosphingobium* (6.56%) and
341 *Chryseolinea* (5.42%) might be partially relevant to membrane fouling. On the other hand,
342 the microorganisms which are able to degrade membrane fouling-induced substances (e.g.
343 polysaccharides (SMP_C and LB-EPS_C), proteins (SMP_P and LB-EPS_P)) and mitigate
344 membrane fouling were detected at low levels (< 1.60%), including *Reyranella*,
345 *Thermogutta*, *Tepidisphaera* and *Comamonas*, except for *Pirellula* at 2.74% and *Kofleria* at
346 3.48% (Inaba et al., 2018; Lang et al., 2014; Liu et al., 2018; Peng et al., 2019; Zheng et al.,
347 2019; Zhou et al., 2017b; Zhu et al., 2017). When TMP reached above 35 kPa, serious
348 membrane fouling in the CMBR could be induced by the enrichment of filamentous
349 bacteria such as *Sphaerotilus*, *Thiothrix* and *Haliscomenobacter* at 8.95%, 8.28% and
350 8.16%, respectively. *Sphaerotilus* enables production of large assemblage and more EPS,
351 thus facilitating colonization and biofilm formation on membrane surface (Peng et al.,
352 2019). Moreover, *Thiothrix* and *Haliscomenobacter* also favor generation of extracellular
353 polymers (i.e. LB-EPS) and negatively influence sludge settleability (Gao et al., 2014; Gu
354 et al., 2018). In addition, the presence of high levels of *Novosphingobium*, *Povalibacter* and
355 *Chryseolinea* (7.78%, 6.82% and 6.23%, respectively) might also aggravate membrane
356 fouling (Choi et al., 2017; Matar et al., 2017; Xu et al., 2018). Furthermore, *Acinetobacter*,
357 which is related to the production of extracellular polysaccharides (SMP_C and LB-EPS_C)
358 (Abdel-El-Haleem et al., 2003), was detected at 6.54% at the end of the experiment. Thus
359 membrane fouling was more severe for the CMBR.

360 **Fig. 3**

361 **Fig. 4.**

362

363 GemFloc™ addition could enhance the variety of microbial community structure which
364 helped to improve sludge properties and reduce membrane fouling in the G-MBR. The
365 presence of *Terrimonas* positively affects flocculation performance of suspended sludge
366 and promotes aggregation of sludge flocs by secreting extracellular polymers with
367 hydrophobic components (Zhao et al., 2019). *Thauera* favors EPS generation, especially
368 proteins as hydrophobic components contributing to cell aggregation and floc formation
369 (Dong et al., 2017; Zhang et al., 2018). When TMP was low at 10-16 kPa, great abundance
370 of *Terrimonas* and *Thauera* (4.76% and 4.34%, respectively) might contribute to better
371 flocculation ability and aggregation of sludge flocs through generating more TB-EPS_p.
372 *Kofleria* (7.72%), *Pirellula* (5.65%), *Reyranella* (4.14%), *Thermogutta* (2.16%) and
373 *Tepidisphaera* (1.63%) were also responsible for reduced proteins (SMP_p and LB-EPS_p)
374 and polysaccharides (SMP_c and LB-EPS_c). The high hydrophobicity of sludge flocs might
375 be ascribed to the high presence of *Pseudomonas* and *Rhodobacter* (2.74% and 1.41%,
376 respectively) (Chao et al., 2014; Sutherland et al., 2001). After terminating the experiment
377 (TMP > 35 kPa), the abundance of *Kofleria* increased (8.22%), which could explain the
378 evidently less SMP_c and LB-EPS_c, while high levels of *Reyranella* (4.75%) and *Pirellula*
379 (4.32%) led to less SMP_c, SMP_p, LB-EPS_c and LB-EPS_p. In addition, the proportion of
380 *Flaviumibacter* at 4.16% resulted in larger size of sludge flocs via providing structural
381 network during the experiment (Luo et al., 2015). Nevertheless, the decline in *Terrimonas*
382 (4.40%) and *Thauera* (4.26%) might deteriorate flocculation and aggregation ability of
383 suspended sludge to some extent. The microorganisms contained greater abundance of

384 *Thermogutta* (4.03%), which might potentially induce more accumulation of SMP_C and
385 $LB-EPS_C$. Overall, the abundant *Terrimonas*, *Thauera* and *Thermogutta* were the main
386 contributor to aggravated membrane fouling in the G-MBR.

387 Compared to the CMBR, the G-MBR contained more abundant bacterial population
388 giving rise to better sludge properties and membrane permeability but less microorganisms
389 aggravating membrane fouling. Additionally, more diverse microbial communities were
390 found in the G-MBR than those in the CMBR, especially at high TMP (> 35 kPa), which
391 also favored fouling control. As an aerobic bacterium, *Arenimonas* can also degrade various
392 sugars and amino acids (Cui et al., 2019). Hence, the presence of *Flaviumibacter*,
393 *Reyranella*, *Pirellula*, *Thauera*, *Thermogutta*, *Arenimonas*, *Rhodobacter*, *Comamonas* and
394 *Pseudomonas* in the G-MBR (1.87%-4.75%) was associated with the enhanced sludge
395 properties (i.e. less proteins and polysaccharides, higher hydrophobicity, better sludge
396 aggregation). On the other hand, genera *Povalibacter*, *Acinetobacter* and *Chryseolinea*
397 were only detected in the CMBR at great abundance (6.23%-6.82%), which were closely
398 linked with the accumulation of SMP_C and $LB-EPS_C$ and further serious membrane fouling.
399

400 4. Conclusions

401 The effectiveness of GemFloc™ on membrane fouling reduction in MBR was
402 evaluated for real municipal wastewater treatment. Compared to the CMBR, GemFloc™
403 could alleviate membrane fouling, reduce SMP and LB-EPS, increase ratio of SMP_p/SMP_C
404 and $LB-EPS_p/LB-EPS_C$, enlarge floc size, and increase TB-EPS_p, zeta potential and RH,
405 thus decreasing R_C and R_p . Moreover, GemFloc™ addition induced higher diversity of

406 microbial community and greater abundance of special functional microorganisms (e.g.
407 *Arenimonas*, *Flaviumibacter*), which enhanced sludge properties and alleviated membrane
408 fouling. Thus GemFloc™ could be a promising novel biofloculant to control membrane
409 fouling.
