1 **Abstract**

2 This paper investigates soil fluidisation at the microscale using the Discrete Element Method  
3 (DEM) in combination with the Lattice Boltzmann Method (LBM). Numerical simulations  
4 were carried out at varying hydraulic gradients across the granular assembly of soil, and the  
5 development of localised hydraulic gradients, the contact force distribution, and the associated  
6 fabric changes were investigated. The novelty of this study includes microscale findings which  
7 suggest that a critical hydromechanical state inducing fluid-like instability of a granular  
8 assembly can initiate when substantial increase in grain slipping associated with reduced  
9 interparticle contacts suddenly occur. Based on these results, a new micro-mechanically  
10 inspired criterion is proposed to characterise the transformation of granular soil from a stable  
11 solid phase to an hydromechanically unstable state. The constraint ratio (number of constraints  
12 in relation to the degrees of freedom) is introduced to portray the relative slip between particles  
13 and the loss of interparticle contacts within the granular fabric. Its magnitude of unity  
14 corresponds to the condition of zero effective stress, representing the critical hydromechanical  
15 state. In a practical sense, the results of this study reflect the phenomenon of subgrade mud  
16 pumping that occurs in railways upon the passage of heavy haul trains at certain axle loads and  
17 speeds.

19 Ratio, Critical Hydraulic Gradient

20 =====

## 21 **1. Introduction**

22 A major problem leading to railroad instability that creates immense maintenance costs is  
23 related to the degradation of the soft subgrade and its potential for fluidisation or mud-pumping  
24 [1-5]. In this context, fluidisation is defined as when saturated soils are exposed to excessive  
25 hydraulic gradients and lose their intergranular contacts to transition into a fluid-like state. As  
26 a result, this slurry of fine particles migrates (pumps) into the overlying coarser ballast layer,  
27 hence the commonly used term mud-pumping, as investigated experimentally [2, 4, 6]. These  
28 laboratory tests enable a better understanding of the hydromechanical behaviour of the  
29 subgrade soils, but primarily at the macroscale. From a micromechanical perspective, i.e., at  
30 the grain level, slippage and/or breakage of the interparticle contacts and the resulting fabric  
31 evolution may initiate the transition from a hydromechanically stable to an unstable state that  
32 is still not fully understood.

33 The Discrete Element Method (DEM) is a useful tool for assessing the micromechanics of  
34 a granular medium [7, 8] that has been effectively used to study the evolution of interparticle  
35 contacts and fabric during shear using the scalar and directional parameters [9, 10]. The  
36 coordination number (number of contacts per particle in the granular assembly) is a  
37 fundamental microscale fabric descriptor for characterising granular medium [10, 11].  
38 Nonetheless, the state of interparticle contacts and fabric during fluid flow has rarely been  
39 considered. In addition, the constraint ratio, defined by the ratio of the number of constraints  
40 to the number of degrees of freedom within the particle system [12], can be used to represent  
41 the relative slip and loss of interparticle contacts during instability. However, none of past  
42 DEM studies have defined any quantitative parameters to describe the rational mechanisms of  
43 soil fluidisation in contrast to more commonly observed undrained failures of saturated soils.

44 The primary scope of this paper includes an attempt to describe and quantify the critical  
45 hydromechanical conditions corresponding to the fluidisation phenomenon with special

46 attention to granular soil at the microscale, adopting the concepts of the coordination number  
47 and the constraint ratio, as mentioned above. For the first time, a comprehensive assessment of  
48 different microscale aspects in relation to fluidisation is introduced in the current study,  
49 including an original micro-condition representing the inception of hydraulic failure of a  
50 saturated soft subgrade. Indeed, the DEM can be used in combination with Computational Fluid  
51 Dynamics (CFD) to study internal erosion and soil fluidisation in detail [13-16]. Neither of  
52 these studies could accurately quantify the critical hydromechanical conditions leading to  
53 potential fluidisation from a microscale perspective, so a more insightful microscale study of  
54 this instability process is needed.

55 Given the above, this study uses a combined fully resolved LBM-DEM approach that is  
56 becoming increasingly popular to study fluid-particle interactions [17-19]. The advantages of  
57 the fully resolved approaches over unresolved approaches include (a) the ability to produce a  
58 much finer mesh size, i.e., finer than the particles that can simulate true experimental  
59 conditions, (b) a higher computational speed when run on parallel computers and, (c) the  
60 relative feasibility of implementation in complex geometries of porous media [20, 21]. In  
61 addition, the LBM is based on the kinetic theory of gases and represents a fluid through an  
62 assembly of particles that go through successive collision and propagation processes. This  
63 enables the calculation of the macroscopic fluid velocity and the pressure as a function of the  
64 momentum of these particles [21, 22].

65 The application of micromechanical modelling to a given volume of a porous medium will  
66 have inevitable size-effects when compared to real-life analysis. In the field, the seepage path  
67 lengths are large (e.g. several meters in dam sites, landslide areas etc.) compared to small-scale  
68 laboratory specimens, so one would expect the measured hydraulic gradients to be significantly  
69 smaller and generally less than unity [23]. In contrast to FEM and FDM analyses based on  
70 continuum mechanics for larger soil domains, the DEM analysis often becomes inefficient in

71 terms of computational time when a large soil volume is considered. As a result, for  
 72 convergence of output to an acceptable accuracy, only a limited soil area can be usually  
 73 analysed using DEM, hence the computed hydraulic gradients tend to be larger [24-26].

74 **Lattice Boltzmann Method (LBM) combined with Discrete Element Method (DEM)**

75 The theoretical formulations of the LBM-DEM approach are described as follows:

76 *2.1 Fluid equations*

77 The governing Boltzmann equation is written as [27]:

$$78 \quad \frac{\partial f_{\alpha}(x, t)}{\partial t} + e_{\alpha}^v \nabla f_{\alpha}(x, t) = \Omega_{\alpha} \quad (\alpha = 1, 2, \dots, N) \quad (1)$$

79 where  $f_{\alpha}(x, t)$  is the particle distribution function in the  $\alpha$  direction,  $e_{\alpha}^v$  is the microscopic fluid  
 80 velocity and  $\Omega_{\alpha}$  is the collision operator, and  $t$  is the time. Equation (1) can be discretised on  
 81 a regular lattice using a unique finite difference method, and the lattice-Boltzmann equation  
 82 with the Bhatnagar-Gross-Krook (BGK) collision operator for a Newtonian fluid is written as  
 83 [27, 28]:

$$84 \quad f_{\alpha}(x + e_{\alpha}^v \Delta t, t + \Delta t) - f_{\alpha}(x, t) = \Omega_{\alpha}^{BGK} \quad (2)$$

85 where  $\Omega_{\alpha}^{BGK}$  is the BGK collision operator, and  $\Delta t$  is the time-step.

86 Each time step is divided into two sub-steps, i.e., the collision and streaming step, and the  
 87 collision step is written as:

$$88 \quad f_{\alpha}(x, t^*) = f_{\alpha}(x, t) + \Omega_{\alpha}^{BGK} \quad (3)$$

89  $f_{\alpha}(x, t^*)$  and  $f_{\alpha}(x, t)$  are the particle distribution functions after and before the collision,  
 90 respectively, and  $t^*$  is the time after the collision. In the streaming step, the  $f_{\alpha}(x, t^*)$  is  
 91 propagated over the lattice grid as follows:

92  $f_\alpha(x + e_\alpha^v \Delta t, t + \Delta t) = f_\alpha(x, t^*)$  (4)

93 *2.2 Fluid-particle interaction*

94 The participation of solid particles in the fluid is achieved by introducing an additional  
 95 collision term ( $\Omega_\alpha^s$ ) in Equation (3) as suggested by Noble & Torczynski (1998) [29]:

96  $f_\alpha(x, t^*) = f_\alpha(x, t) + [1 - B] \Omega_\alpha^{BGK} + B \Omega_\alpha^s$  (5)

97  $B = \frac{\varepsilon_s (\tau / \Delta t - 1/2)}{(1 - \varepsilon_s) + (\tau / \Delta t - 1/2)} = (0,1)$  (6)

98 where  $\varepsilon_s$  is the solid fraction in the fluid cell volume,  $B$  is a weighting function for correcting  
 99 the collision phase of the lattice-BGK equation due to the presence of solid particles, and  $\tau$  is  
 100 the relaxation time (Appendix 1). The method for calculating the solid fraction for the moving  
 101 particles is described by [22].

102 The non-equilibrium part of the particle distribution function is bounced back and  $\Omega_\alpha^s$  is  
 103 computed using:

104  $\Omega_\alpha^s = f_{-\alpha}(x, t) - f_\alpha(x, t) + f_\alpha^{eq}(\rho_f, v^p) - f_{-\alpha}^{eq}(\rho_f, u)$  (7)

105 where  $v^p$  is the velocity of solid particle  $p$  at time  $t + \Delta t$  at the node,  $u$  is the macroscopic  
 106 fluid velocity, and the notation  $f_{-\alpha}$  is the rebound state obtained by reversing all microscopic  
 107 fluid velocities, i.e.,  $e_\alpha^v$  to  $e_{-\alpha}^v$ . Further details on the fluid equations and the fluid-particle  
 108 interaction are described in Appendix A.

109 *2.3 Validation*

110 Figure 1 shows the flowchart of the LBM-DEM approach described above. The DEM  
 111 calculation cycles are within the LBM cycles. In order not to impair the accuracy of the  
 112 simulation, a suitable interval for the information exchange between 2 phases was chosen [30].

113 Although the coupled LBM-DEM approach was previously validated by Indraratna et al.  
114 (2021a) [18] with experimental observations of fluidisation, the transient motion of the  
115 particles in the fluid was not quantified. In this regard, this study attempts to validate the motion  
116 of a single particle falling into the fluid with different particle Reynold's numbers ( $Re_p$ ). This  
117 validation is carried out by comparing the numerical results with the experimental observations  
118 by Ten Cate et al. (2002) [31]. Figures 2(a) and 2(b) show the schematic sketch and the  
119 modelled problem using the LBM-DEM approach, respectively. Table 1 shows the fluid  
120 properties used with lattice resolution ( $N$ ) = 5 (particle diameter corresponds to 5 fluid cells)  
121 and the relaxation time ( $\tau$ ) = 0.53. It is noteworthy that  $N = 5$  was chosen after a preliminary  
122 sensitivity analysis in which the simulation was run with  $N = 5, 7$  and 10. The results showed  
123 insignificant difference in the numerical output when  $N > 5$ . Figures 2(c) and 2(d) show an  
124 excellent agreement between the numerical and experimental results of the position and  
125 velocity of the falling particle over time at different Reynold's numbers. Hence, it could be  
126 justified with confidence that the LBM-DEM approach would reasonably predict the transient  
127 motion of the particles in the fluid with these selected numerical parameters.

## 128 **2. Simulating Soil Specimen Fluidisation**

### 129 *3.1 Simulation approach*

130 Three-dimensional LBM-DEM simulations were carried out using the Hertz-Mindlin  
131 contact model (Appendix B) with the Young's modulus and the Poisson's ratio of the particles  
132 as 70 GPa and 0.3, respectively (Thornton, 2000). The particle density was set to 2650 kg/m<sup>3</sup>,  
133 and the rigid boundary walls were used. The gravitational deposition method was used for  
134 sample preparation [32], whereby the acceleration due to the force of gravity of the particles  
135 was set to 9.81 m/s<sup>2</sup>. The particles were initially created in a larger volume with no overlap and  
136 then dropped under gravity. The particles were allowed to settle until equilibrium was reached,  
137 thereby ensuring that the coordination number remained constant for a sufficient number of

138 numerical cycles. The sample was prepared in a dense state by setting the coefficient of friction  
139 ( $\mu_s$ ) to 0 [32, 33]. Subsequently,  $\mu_s$  was changed to 0.30, and the particles were re-equilibrated  
140 with a sufficient number of numerical cycles before the particles became saturated with the  
141 fluid. The  $\mu_s$  value used in this study is in the range of real quartz particle values that can be  
142 determined experimentally with a micromechanical interparticle loading apparatus [34]. It is  
143 assumed that the particle-wall contact parameters correspond to the particle-particle contact  
144 parameters [35, 36].

145 The fluid density was set to  $1000 \text{ kg/m}^3$  with a kinematic viscosity of  $1 \times 10^{-6} \text{ m}^2/\text{s}$  according  
146 to pure water properties at  $20 \text{ }^\circ\text{C}$  and 1 atmosphere (101 kPa). The resolution of the fluid lattice  
147 was chosen with at least 5 lattices in each particle, i.e., the smallest particle diameter  
148 corresponds to at least 5 fluid cells with regard to the validation of the single-particle displaced  
149 downwards into the fluid described previously. A relaxation parameter close to but greater than  
150 0.50 was chosen, and the Mach number was kept below 0.1, inspired by the need for improved  
151 accuracy, as explained elsewhere by Han et al. (2007) [20]. The fluid flow was initiated with  
152 the relevant inlet and outlet pressure boundary conditions, and no-slip conditions were imposed  
153 on the boundaries perpendicular to the flow. For each hydraulic gradient applied, the flow was  
154 continued over a sufficient period of time until a steady-state condition was attained.

### 155 *3.2 Particle size distribution and homogeneity of the sample*

156 Figure 3(a) shows the particle size distribution of the selected sample from an experimental  
157 study carried out earlier by Indraratna et al. (2015) [24]. Figure 3(b) shows the three-  
158 dimensional DEM-based sample with 17607 particles, and the direction of fluid flow is also  
159 shown, i.e., the  $z$ -direction. Figure 3(c) shows the division of the sample into 10 different inner  
160 layers. The ratio of the lateral dimension of the simulation domain to the maximum particle  
161 diameter was kept greater than 12 in order to obtain a representative elementary volume (REV)

162 and avoid the boundary effects. A local decrease in the void ratio occurs near the rigid  
 163 boundaries [8]; hence, the bottom boundary layer (besides the rigid bottom boundary) was  
 164 neglected in order to nullify the boundary effects [37]. The thickness of each layer was chosen  
 165 to be more than twice the maximum particle diameter to define a REV [37]. The stresses at the  
 166 boundaries do not reflect the actual material response; therefore, the interaction of the particles  
 167 in each layer with the lateral boundaries was not taken into account.

168 Figure 3(c) shows the similar initial void ratios of all layers, indicating the REV in each  
 169 layer, and the initial homogeneity of the sample was further confirmed by considering the  
 170 variances in the void ratios as reported by Jiang et al. (2003) [38]:

$$171 \quad S^2 = \frac{1}{n_L - 1} \sum_{k=1}^{n_L} (e_{oi}^k - e_{oi}^{avg})^2 \quad (8)$$

172 where  $S$  is the variance of the void ratios,  $n_L$  is the total number of layers,  $e_{oi}^k$  is the initial void  
 173 ratio of the  $k^{th}$  layer, and  $e_{oi}^{avg}$  is the initial void ratio of the entire sample. The  $S^2$  value for the  
 174 sample in Fig. 3(c) is  $2.72 \times 10^{-5}$ , which is sufficiently low to classify the sample as  
 175 homogenous with respect to the REV in each layer. The overall void ratio of the numerical  
 176 sample is the same as that of the experimental sample. Note that the void ratio does not take  
 177 into account the particulate structure of the granular medium. Figure 3(d) shows a close-up  
 178 view of the particles modelled in the fluid mesh. It can be seen that the mesh size is much  
 179 smaller than the particle and pore size, in contrast to the conventional unresolved approach  
 180 with the Navier-Stokes equation.

### 181 3.3 Calibration

182 Figure 4 shows the calibration of the numerical model of soil fluidisation by comparing the  
 183 flow curves obtained from the LBM-DEM approach and those of an earlier experimental study

184 (Indraratna et al., 2015) [24]. The flow curves obtained from the LBM-DEM approach and the  
185 experimental study agree with each other. The overall hydraulic gradient ( $i_o$ ) is derived from  
186 the pressure difference between the top and bottom of the specimen, i.e.,  $i_o = \Delta P / \gamma_w L$ , where  
187  $\gamma_w$  is the unit weight of water. The overall critical hydraulic gradient ( $i_{o,cr}$ ) predicted by the  
188 LBM-DEM approach was 1.050 and the experimental value was 1.180. These values are in  
189 acceptable agreement with one another.

190 It is important to note that the values of  $i_{o,cr}$  predicted by the current LBM-DEM approach  
191 and the previous authors' experimental studies [24] are larger than the theoretical values based  
192 on the upward flow heave phenomenon (i.e., zero effective stress) described by Tezaghi [39].  
193 This is because such classical theories ignore interparticle friction within the microscale soil  
194 fabric, and also assume frictionless boundaries in the analysis. In contrast, the current DEM  
195 simulation considered a friction coefficient of 0.3 for the wall-particle interaction as well as  
196 interparticle contacts, resulting in an increase of the critical hydraulic gradients in the  
197 micromechanical fluid-particle coupled approach. The current computational results for  
198 hydraulic gradients are in agreement with several past micromechanical and experimental  
199 studies [25, 26, 36].

### 200 **3. Results and Discussion**

#### 201 *4.1 Stress-hydraulic gradient evolution*

202 Figure 5 shows the stress-hydraulic gradient space where the local hydraulic gradients ( $i_{hyd}$ )  
203 are plotted against the normalised Cauchy effective stresses ( $\sigma'_{zz} / \sigma'_{zz0}$ ) of particles in a given  
204 layer in the fluid flow direction at any time. Here,  $\sigma'_{zz}$  is the Cauchy effective stresses of the  
205 particles in a layer at any time, and  $\sigma'_{zz0}$  is the initial Cauchy effective stresses of the particles  
206 in that particular layer. The local hydraulic gradients are computed based on the pressure  
207 difference across each layer, i.e.,  $i_{hyd} = \Delta P_{layer} / \gamma_w L_{layer}$ , where  $\Delta P_{layer}$  is the pressure drop

208 across the layer and  $L_{layer}$  is the thickness of each layer. The  $\sigma'_{zz}$  is obtained using the particle-  
 209 based stresses via the following second-order stress tensor equation [40].

$$210 \quad \sigma'_{ij} = \frac{1}{V} \sum_{p=1}^{N_p} \sigma_{ij}^{p'} V^p \quad (10)$$

211 where  $V$  is the volume of the layer or the selected region,  $V^p$  is the volume of particle  $p$  in the  
 212 region,  $N_p$  is the number of particles in the layer, and  $\sigma_{ij}^{p'}$  is the average stress tensor within a  
 213 particle  $p$  and is given by:

$$214 \quad \sigma_{ij}^{p'} = \frac{1}{V^p} \sum_{c=1}^{N_c^p} |x_i^c - x_i^p| n_i^{c,p} f_j^c \quad (11)$$

215 where  $f_j^c$  is the force vector in the  $j^{th}$  direction at contact  $c$  with the location  $x_i^c$ ,  $x_i^p$  is the  
 216 location of the particle's centroid,  $n_i^{c,p}$  is the unit normal vector from the particle's centroid to  
 217 the contact location and  $N_c^p$  is the number of contacts on the particle  $p$ . Note that Equations  
 218 (10) and (11) compute the effective stresses directly from the contact moments and not  
 219 according to the Terzaghi's concept used in the macroscale laboratory studies. Reynold's  
 220 stresses are negligible up to the beginning of fluidisation and are not taken into account.

221 The onset of fluidisation of the soil is associated with hydraulic and stress conditions, i.e.,  
 222 the hydromechanical conditions. The effective stresses decrease with increasing local hydraulic  
 223 gradients in each layer. The onset occurs at a critical hydraulic gradient when the effective  
 224 stresses drop to zero. The evolution of the stress-gradient of each layer is not the same. The  
 225 stress-gradient paths of Layers 1-6 are approximately linear with a slope of -1. In contrast to  
 226 the theoretical linear stress-gradient paths presented by Li and Fannin (2012) [41], the stress-  
 227 gradient paths of Layers 7-10 (lower layers) are nonlinear until failure. The failure initiates  
 228 when the effective stress of Layer 10 approaches zero. At the same time, Layers 1-9 show

229 residual stresses due to the motion of the particles in the form of clusters. These residual  
230 stresses decrease as the particles in the cluster would lose further contacts over time after onset  
231 until complete fluidisation occurs.

#### 232 *4.2 Broken contacts*

233 Figure 6 shows the development of the broken contacts ( $B_R$ ) compared to the normalised  
234 effective stresses ( $\sigma'_{zz}/\sigma'_{zz0}$ ).  $B_R$  is the percentage of interparticle contact losses in the initial  
235 number of contacts in the corresponding layer. The value of  $B_R$  increases with increasing  
236 hydraulic gradient and decreasing effective stresses. Contact is lost when the normal contact  
237 force due to hydrodynamic forces becomes zero. When the fluid flows, the contacts break off,  
238 and new contacts are also formed in the layer. The sharp drop in  $B_R$  represents the critical  
239 hydromechanical state where the contacts are notably lost. The granular assembly would  
240 become a fully fluid-like material when the number of unconnected particles increases to the  
241 maximum due to the breakage of the contacts. In other words, most of the particles would  
242 simply float without any contact. It can also be seen that the contact losses in the lower layers  
243 are greater than in the upper layers, which shows that more particles lose contact at the bottom  
244 and migrate upwards with the fluid flow if the constrictions are wide enough. The value of  $B_R$   
245 at the critical hydraulic gradient is about 5% in Layer 1 and 17% in Layer 10, and it increases  
246 considerably with a further slight increase in the hydraulic gradient applied across the soil  
247 specimen.

#### 248 *4.3 Mechanically stable particles*

249 Figure 7 shows the evolution of the fraction of mechanically stable particles ( $M_s$ ) with  
250 normalised effective stresses ( $\sigma'_{zz}/\sigma'_{zz0}$ ) under increasing hydraulic gradients. The  
251 mechanically stable particles are those that participate in the stable network of force  
252 transmission. The value of  $M_s$  is defined by [42]:

253 
$$M_s = \frac{N_p^{\geq 4}}{N_p} \quad (12)$$

254 where  $N_p^{\geq 4}$  is the number of particles with at least 4 or more contacts. Particles with zero  
255 contacts that do not participate in the stable network of force transmission are called rattlers or  
256 unconnected particles; hence, they are excluded. The particles with 1, 2, and 3 contacts are  
257 temporarily stable for a limited time, so they are also neglected in the above equation.

258 It should be noted that the values of  $M_s$  are always smaller than 1 across all layers since the  
259 temporarily stable particles are also present at the hydrostatic state. The initial values of  $M_s$  are  
260 higher in the lower layers than in the upper layers. The values of  $M_s$  decrease across all layers  
261 with a reduction in the magnitude of effective stresses. This reduction becomes significant at  
262 the critical hydraulic and stress conditions that indicate the breakup of the clusters of  
263 mechanically stable particles. The results show that a critical value of  $M_s \approx 0.75$  is found for  
264 all layers, below which the fluid-like behaviour of the soil is observed.

#### 265 *4.4 Evolution of the soil fabric*

266 Figure 8 shows a conceptual model that describes the differences in the fabrics of two-  
267 particle systems where particles with two different geometrical arrangements are placed, where  
268 the void ratios of both arrangements are the same. However, the number of interparticle  
269 contacts is different due to the dissimilarity of the fabrics of the particulate systems. It is  
270 noteworthy that the geometric arrangement of the particles is more important than the void  
271 ratio when it comes to the strength of the granular assembly [12]. Similar initial void ratios of  
272 all layers indicate that the number of particles in each layer is the same. However, the number  
273 of interparticle contacts may vary due to the different geometrical configurations of the  
274 particles. During fluid flow, the number of particles in each layer remains unchanged until

275 fluidisation begins, while the geometrical rearrangement of the particles can occur, mainly  
276 attributed to the interparticle contacts within the layer slip and/or break.

277 To assess the evolution of soil fabric under fluid flow, this study uses a scalar approach [11]  
278 to quantify the fabric with a scalar fabric descriptor called the coordination number ( $Z$ ) and is  
279 computed as follows [10].

$$280 \quad Z = \frac{2N_c}{N_p} \quad (13)$$

281 where  $N_c$  is the number of contacts and is multiplied by 2 since each contact is shared by two  
282 different particles.

283 Figure 9 shows the distribution of the  $Z$  at the hydrostatic state and the onset of soil  
284 fluidisation, taking into account three distinct cases:

- 285 (a) all particles,
- 286 (b) particles with diameters ( $d_p$ )  $\geq d_{50}$  (where  $d_{50}$  is the particle size that is 50% finer by mass),  
287 and
- 288 (c) particles with  $d_p \geq d_{85}$  (where  $d_{85}$  is the particle size that is 85% finer by mass)

289 Figure 9(a) shows that the distribution of the coordination numbers at the hydrostatic state  
290 across different layers is somewhat dissimilar when all particles are considered. This difference  
291 is enhanced when larger particle sizes are taken into consideration (Figures 9(c) & 9(e)), which  
292 is reflected by a dissimilarity in the fabric of all layers despite similar void ratios. This fabric  
293 dissimilarity is ascribed to the influence of gravity during the sample preparation phase. The  
294 curves of the lower layers are on the right-hand side and show higher values of the coordination  
295 numbers than those of the upper layers. The slight difference in the evolution of local hydraulic  
296 gradients and effective stresses through each layer, as previously described, is due to this slight  
297 dissimilarity of the particles' fabric in the layers. It is appealing to note that at the onset of

298 fluidisation, the distributions of the coordination numbers of all layers converge and become  
 299 similar (Figures 9(b), 9(d), & 9(f)). The median value of the coordination number ( $Z_{50}$ ) is 4  
 300 when all particles in the granular medium of the layer are taken into account (Figure 9(b)).  
 301 Thus, at the onset of fluidisation, the distributions of the interparticle contacts are uniform and  
 302 show a similar fabric for all soil layers.

303 Figure 10 shows average coordination numbers ( $Z_{avg}$ ) versus normalised effective stresses  
 304 ( $\sigma'_{zz}/\sigma'_{zz0}$ ), where the initial (at the hydrostatic state) average coordination of Layer 10 is the  
 305 highest (i.e.,  $Z_{avg} = 5.405$ ), while Layer 1 has the lowest (i.e.,  $Z_{avg} = 4.811$ ). As the normalised  
 306 effective stresses decrease, the values of  $Z_{avg}$  decrease across all layers, and so does the  
 307 difference between them. Although each layer initially had a different fabric, the  $Z_{avg}$  of all  
 308 layers has evolved to become the same, i.e., 4.6 at critical hydromechanical state.

#### 309 *4.5 Slipping index*

310 Figure 11 shows the distribution of the slipping index ( $S_i$ ) of the selected Layer 10. Here,  
 311 all layers show an almost similar development in the slipping index as the local hydraulic  
 312 gradient increases. The slipping index ( $S_i$ ) is defined by [42]:

$$313 \quad S_i = \frac{f^T}{\mu_s f^N} \quad (14)$$

314 Slipping or the plastic contacts occur when the tangential contact force ( $f^T$ ) has fully mobilised  
 315 the friction, i.e.,  $S_i = 1$ . The contacts with  $S_i < 1$  are the elastic contacts and  $f^T$  is independent  
 316 of  $f^N$  in such contacts. Note that contacts that have already been lost are not taken into account  
 317 when calculating  $S_i$ .

318 The results show that a small proportion of the contacts slip even at the hydrostatic state, as  
 319 the static buoyancy forces act on the particles when they are saturated with the fluid. As the

320 local hydraulic gradients increase, the elastic contacts decrease, and the slipping contacts  
321 increase. The hydrodynamic forces from the seepage flow tend to move the particles, causing  
322 a change in the magnitudes of the resisting tangential contact force and the normal contact  
323 force. As a result, a slip is caused when the elastic tangential contact force reaches the Coulomb  
324 cut-off, i.e.,  $f^T = \mu_s f^N$  and this slipping of the particles occurs in the weak contacts ( $f^N <$   
325  $f_o^{N,avg}$ ). At  $i_{hyd} \leq 1$ , the proportion of slipping contacts in the total number of contacts in the  
326 layer is  $\leq 10\%$ , while it is around 17% at the critical  $i_{hyd} = 1.251$  as shown in Figure 11(g).  
327 Thereafter, this proportion of slipping contacts increases steeply with a further, albeit slight,  
328 increase in the hydraulic gradient. It is noteworthy that the maximum tangential force is  
329 controlled by the value of  $\mu_s$ . Therefore, the value of  $\mu_s$  has a profound influence on the  
330 proportion of slipping contacts and consequently on the macroscale behaviour of the granular  
331 assembly.

#### 332 4.6 Constraint ratio

333 Figure 12 shows a three-dimensional representation of the constraint ratio ( $R$ ) versus local  
334 hydraulic gradients ( $i_{hyd}$ ) and normalised effective stresses ( $\sigma'_{zz}/\sigma'_{zz0}$ ). The constraint ratio for  
335 a three-dimensional particle system that only takes the sliding resistance into account is given  
336 by (Cundall & Strack, 1983):

$$337 \quad R = \frac{N_{ct}}{N_d} = \frac{N_c(3 - 2S_c)}{6N_p} \quad (15)$$

338 where  $N_{ct}$  is the number of constraints,  $N_d$  is the number of degrees of freedom, and  $S_c$  is the  
339 fraction of slipping contacts in the total number of contacts at a given point in time. For an  
340 idealised granular medium with  $\mu_s = \infty$ ,  $N_{ct} = 3N_c$  and  $N_d = 6N_p$ . The realistic granular  
341 medium, however, would have a finite value of  $\mu_s$ ; therefore, the two tangential force  
342 constraints on contacts subject to slipping vanish and are excluded from the total number of

343 constraints given in equation (15). Theoretically, if  $N_{ct} > N_d$ , the granular assembly is  
344 considered to be over-constrained or mechanically stable, and if  $N_{ct} = N_d$ , it is considered to  
345 be in a critical or transitional state; otherwise, it is unstable. Note that  $R$  represents both slipping  
346 and loss of contacts in the particle systems, whereas the coordination number does not take into  
347 account the slipping of particles [10].

348 The constraint ratio in each layer decreases according to the nonlinear power laws when the  
349 normalised effective stresses decrease, and it decays exponentially after the onset of the soil  
350 fluidisation (Fig. 12). The initial mild slope shows that at the relatively low  $i_{hyd}$  values, i.e.,  $i_{hyd}$   
351  $< 1$ , the particles slip less and have minimal loss of contacts. The abrupt change in slope after  
352 onset is triggered by substantial slipping and the associated rapid loss of interparticle contacts.  
353 The point at which the slope value changes represents the critical microscale hydromechanical  
354 state or the onset of soil fluidisation. This point is marked as a transition from a  
355 hydromechanically stable to a fluid-like state, as shown in Fig. 12(b). This critical  
356 hydromechanical state corresponds to  $R \approx 1$ , with effective stresses  $\approx 0$  at the critical hydraulic  
357 gradient. In this respect, the soil is hydromechanically stable when  $R$  is greater than 1, while it  
358 is in a transition state from a hydromechanically stable to a fluid-like state when  $R$  is 1;  
359 otherwise, it corresponds to a slurry or fluid-like state. Complete fluidisation of the soil  
360 specimen occurs when almost all interparticle contacts are lost, which is represented by a  
361 constraint ratio that is significantly below 1.

#### 362 **4. Conclusions**

363 This study assessed the hydromechanical state of soil fluidisation from a micromechanical  
364 perspective using the LBM-DEM approach. The good agreement between the model  
365 predictions and the experimental observations in relation to particle motion, fluid flow curves,  
366 and the critical hydraulic gradients confirms the capability and reliability of this hybrid

367 numerical method. Based on the findings of this study, the following salient outcomes can be  
368 drawn:

- 369 • At comparatively low values of the local hydraulic gradient ( $i_{hyd}$ ), i.e.,  $i_{hyd} \leq 1$ , the  
370 proportion of slipping contacts in the total number of contacts of the selected Layer 10  
371 (bottom of the specimen) was  $\leq 10\%$ , while it was approximately 17% at the critical  $i_{hyd}$   
372  $=1.251$ . The extent of slipping contacts increased with a further increase in the hydraulic  
373 gradient applied across the soil specimen.
- 374 • The fraction of mechanically stable particles was generally larger at the deeper layers, but  
375 decreased with the reduction in normalised effective stress during the corresponding  
376 increase in hydraulic gradient. The fluid-like state of soil was triggered when this fraction  
377 of mechanically stable particles dropped below 0.75.
- 378 • The hydrodynamic forces induced by the seepage flow inevitably destabilise and move the  
379 particles within the granular assembly, also resulting in decreased contact forces, thus  
380 creating critical conditions to facilitate particle slipping. The loss of interparticle contacts  
381 was not uniform across the depth of the soil specimen, as this was more pronounced in the  
382 deeper layers when subjected to an upward flow from the base of specimen.
- 383 • At the critical hydraulic gradient, the percentage of interparticle contact losses relative to  
384 the initial number of contacts was non-uniform and varied between 5 and 17% across the  
385 specimen depth. Thereafter, even with a slight increase in the hydraulic gradients, the  
386 breakage of the interparticle contacts appeared to exacerbate.
- 387 • At the onset of fluidisation, the distributions of the coordination numbers across all layers  
388 of the soil specimen became more uniform, with a median value of 4 and an average value  
389 of 4.6, thus representing a more uniform granular fabric across the soil layers.
- 390 • The novel use of the constraint ratio to portray soil instability proved that the granular  
391 assembly was hydromechanically stable when the constraint ratio  $> 1$  and unstable (fluid-

392 like) when the constraint ratio  $< 1$ , thereby establishing the microscale hydromechanical  
393 critical state at the constraint ratio of unity.

401 **Appendix A. LBM-DEM Approach**

402 The  $\Omega_\alpha^{BGK}$ , through which the momentum transfer occurs between the fluid particles when  
 403 they collide, is given by (Bhatnagar et al., 1954):

$$404 \quad \Omega_\alpha^{BGK} = -\frac{\Delta t}{\tau} \left( f_\alpha(x, t) - f_\alpha^{eq}(x, t) \right) \quad (\text{A. 1})$$

405 where  $f_\alpha^{eq}(x, t)$  is the equilibrium distribution function,  $\tau$  is the relaxation time, and is related  
 406 to the kinematic viscosity ( $\nu_f$ ) of the fluid, the lattice spacing ( $\Delta x$ ), and the time step ( $\Delta t$ ) by  
 407 the following relationship:

$$408 \quad \nu_f = \frac{1}{3} \left( \tau - \frac{1}{2} \right) \frac{\Delta x^2}{\Delta t} \quad (\text{A. 2})$$

409 Eq. (A.2) implies that the  $\tau$  value should be greater than 0.5. For a given value of  $\nu_f$  and  $\tau$ , the  
 410  $\Delta t$  is defined according to the chosen  $\Delta x$  by:

$$411 \quad \Delta t = \frac{1}{3\nu_f} \left( \tau - \frac{1}{2} \right) \Delta x^2 \quad (\text{A. 3})$$

412 The  $f_\alpha^{eq}(x, t)$  for the BGK model is given by (Bhatnagar et al., 1954):

$$413 \quad f_\alpha^{eq}(x, t) = \omega_\alpha \rho_f \left( 1 + \frac{3}{c_L^2} e_\alpha^v u + \frac{9}{2c_L^4} (e_\alpha^v u)^2 - \frac{3}{2c_L^2} u^2 \right) \quad (\text{A. 4})$$

414 where,  $\omega_\alpha$  is the weighting factor for the velocity vectors,  $\rho_f$  is the fluid density,  $e_\alpha^v$  is the  
 415 microscopic fluid velocity,  $u$  is the macroscopic fluid velocity, and  $c_L$  is the lattice speed given  
 416 by:

$$417 \quad c_L = \frac{\Delta x}{\Delta t} \quad (\text{A. 5})$$

418 In lattice Boltzmann computations,  $c_L = \Delta x = \Delta t = 1$ , and the discretisation schemes in LBM  
 419 are labelled as  $DdQq$ , where  $d$  is the number of dimensions, and  $q$  represents the number of  
 420 velocity vectors. This study used the  $D3Q19$ , a three-dimensional scheme with 19 velocity  
 421 vectors, including one at rest. Figure A.1 shows the directions of the velocity vectors ( $e_\alpha^v$ ) for  
 422 the  $D3Q19$  scheme and, for the sake of simplicity, their magnitudes are already defined by:

$$423 \quad e_\alpha^v = \begin{cases} (0,0,0) & i = 0 \\ (\pm c_L, 0,0), (0, \pm c_L, 0), (0,0, \pm c_L) & i = 1,2,3,4,5,6 \\ (\pm c_L, \pm c_L, 0), (\pm c_L, 0, \pm c_L), (0, \pm c_L, \pm c_L) & i = 7,8,9,10,11, \dots, 18 \end{cases} \quad (\text{A. 6})$$

424 and the weighing factors are  $\omega_0 = 1/3$ ,  $\omega_{1,2,3,4,5,6} = 1/18$  and  $\omega_{7,8,\dots,18} = 1/36$ .

425 The macroscopic fluid properties, i.e., fluid density ( $\rho_f$ ) and velocity ( $u$ ) can be retrieved at  
 426 each node and given by (Han & Cundall, 2017; Seil et al., 2018):

$$427 \quad \rho_f(x, t) = \sum_{\alpha=0}^{q-1} f_\alpha(x, t) \quad (\text{A. 7})$$

$$428 \quad u(x, t) = \frac{1}{\rho_f} \sum_{\alpha=0}^{q-1} f_\alpha(x, t) e_\alpha^v \quad (\text{A. 8})$$

429 To determine the fluid pressure  $p_f$ , it is assumed that the fluid is slightly compressible, and the  
 430 following state equation is used:

$$431 \quad p_f = c_s^2 \rho_f \quad (\text{A. 9})$$

432 where  $c_s$  is the sound celerity and is defined by:

$$433 \quad c_s = \frac{c_L}{\sqrt{3}} \quad (\text{A. 10})$$

434 Fluid modelled with LBM requires a slight variation in spatial density. An approximate  
 435 incompressibility situation can only be achieved under the condition that the Mach number ( $M$ )  
 436 is small; is therefore kept below 0.1 (Han et al., 2007), and is defined by:

$$437 \quad M = \frac{u_{max}}{c_L} \quad (\text{A. 11})$$

438  $u_{max}$  is the maximum velocity in the fluid flow in physical units. Fluids with lower viscosity  
 439 and turbulent flows can also be simulated with LBM using the Smagorinsky Large Eddy  
 440 Simulation approach (Han et al., 2007; Seil et al., 2018).

441 For the fluid-particle interaction, the force ( $f_f$ ) (without the static buoyancy force) and the  
 442 torque ( $T_f$ ) acting on a particle through the fluid can then be computed by (Noble & Torczynski,  
 443 1998; Seil et al., 2018):

$$444 \quad f_f = \frac{\Delta x^3}{\Delta t} \left[ \sum_n B_n \sum_\alpha \Omega_\alpha^s e_\alpha^v \right] \quad (\text{A. 12})$$

$$445 \quad T_f = \frac{\Delta x^3}{\Delta t} \left[ \sum_n B_n (x^n - x^p) \sum_\alpha \Omega_\alpha^s e_\alpha^v \right] \quad (\text{A. 13})$$

446  $B_n$  is the weighting function in the cell,  $x^n$  is the coordinate of the lattice cell, and  $x^p$  is the  
 447 centre of mass of the particle. Eq. (A.12) does not include the static buoyancy forces; therefore,  
 448 they are applied separately to the particles and the total hydrodynamic force ( $f_{hyd}$ ) on the  
 449 particle, including the static buoyancy force ( $f_{bu}$ ) is given by:

$$450 \quad f_{hyd} = f_f + f_{bu} \quad (\text{A. 14})$$

451 The governing equations of motion of solid particles given by Cundall & Strack (1979),  
 452 with the additional fluid-particle interaction force and the torque, are as follows:

$$453 \quad m^p \frac{dv^p}{dt} = f_g^p + f_{hyd}^p + \sum_{c=1}^{N_c^p} f_j^c \quad (\text{A. 15})$$

$$454 \quad I^p \frac{dw^p}{dt} = T_f^p + \sum_{c=1}^{N_c^p} T_j^c \quad (\text{A. 16})$$

455 where  $m^p$  and  $I^p$  are the mass and the moment of inertia of the particle  $p$ ,  $v^p$  and  $w^p$  are the  
 456 translational and angular velocities of the particle  $p$ ,  $N_c^p$  is the total number of contacts on the  
 457 particle  $p$ ,  $f_j^c$  is the contact force vector in the  $j^{\text{th}}$  direction at contact  $c$  on the particle  $p$ ,  $T_j^c$  is  
 458 the torque that acts on the particle  $p$  due to the tangential contact force at contact  $c$ , and  $f_g^p$  is  
 459 the gravitational force on the particle  $p$ .

## 460 **Appendix B. Hertz-Mindlin Contact Model**

461 Figure B.1 shows the rheological scheme and schematic sketch of the Hertz-Mindlin contact  
 462 model used in this study to simulate the fluidisation of the soil. The normal contact force ( $f^N$ )  
 463 is based on Hertzian contact theory and the tangential contact force ( $f^T$ ) is based on the work  
 464 of Mindlin & Deresiewicz (1989). The  $f^N$  and  $f^T$  have the nonlinear spring and damping  
 465 components. The normal and tangential damping coefficients ( $c_n$  and  $c_t$ ) are related to the  
 466 restitution coefficient as reported by Tsuji et al. (1992). The tangential frictional force follows  
 467 Coulomb's friction law (e.g., Cundall & Strack, 1979).

$$468 \quad f^N = k_n \delta_n - c_n v_n^{rel} \quad (\text{B. 1})$$

469 where  $k_n$  is the elastic constant for normal contact,  $c_n$  is the viscoelastic damping constant for  
 470 normal contact,  $\delta_n$  is the normal component of the displacement at the contact as represented  
 471 by the overlap distance,  $v_n^{rel}$  is the normal component of the relative velocity of two spherical  
 472 particles, and  $k_n$  is given by:

473  $k_n = \frac{4}{3} E^* \sqrt{R^* \delta_n}$  (B. 2)

474 where  $E^*$  is the equivalent Young's modulus and  $R^*$  is the equivalent radius which can be  
 475 written as follows:

476  $\frac{1}{R^*} = \frac{1}{R_i} + \frac{1}{R_j}$  (B. 3)

477  $\frac{1}{E^*} = \frac{1 - \nu_i^2}{E_{y_i}} + \frac{1 - \nu_j^2}{E_{y_j}}$  (B. 4)

478 where  $R_i$  and  $R_j$  are the radius,  $E_{y_i}$  and  $E_{y_j}$  are Young's modulus, and  $\nu_i$  and  $\nu_j$  are the Poisson's  
 479 ratio of each neighbouring spheres in contact. The viscoelastic damping constant ( $c_n$ ) is given  
 480 by:

481  $c_n = -2 \sqrt{\frac{5}{6}} \beta \sqrt{S_n m^*} \geq 0$  (B. 5)

482 where,  $m^*$  is the equivalent mass and is given by:

483  $\frac{1}{m^*} = \frac{1}{m_i} + \frac{1}{m_j}$  (B. 6)

484  $\beta$  and  $S_n$  are given by:

485  $\beta = \frac{\ln e_r}{\sqrt{\ln^2 e_r + \pi^2}}$  (B. 7)

486  $S_n = 2E^* \sqrt{R^* \delta_n}$  (B. 8)

487 where  $e_r$  is the coefficient of restitution. The tangential contact force ( $f^T$ ) is given by:

488  $f^T = k_t \delta_t - c_t v_t^{rel}$  (B. 9)

489 where  $k_t$  is the elastic constant for tangential contact,  $c_t$  is the viscoelastic damping constant  
490 for tangential contact,  $\delta_t$  is the tangential overlap, and  $v_t^{rel}$  is the tangential component of the  
491 relative velocity of two spherical particles, and  $k_t$  is given by:

$$492 \quad k_t = 8G^* \sqrt{R^* \delta_n} \quad (\text{B.10})$$

493 with  $G^*$  as the equivalent shear modulus, and  $c_t$  is written as follows:

$$494 \quad c_t = -2 \sqrt{\frac{5}{6}} \beta \sqrt{k_t m^*} \geq 0 \quad (\text{B.11})$$

495 The  $f^T$  is limited by:

$$496 \quad f^T = \mu_s f^N \quad (\text{B.12})$$

497 where  $\mu_s$  is the coefficient of sliding friction.

498 **Notations**

499 *The following symbols are used in this paper:*

500  $B$  = weighing function to correct the collision phase due to the presence of solid particles,

501  $B_R$  = percentage of broken contacts,

502  $c_L$  = lattice speed,

503  $c_n$  = viscoelastic damping constant for normal contact,

504  $c_s$  = sound celerity,

505  $c_t$  = viscoelastic damping constant for tangential contact,

506  $d_p$  = diameter of the particle,

507  $d_{50}$  = particle size that is 50% finer by mass in the particle size distribution,

508  $d_{85}$  = particle size that is 85% finer by mass in the particle size distribution,

509  $E^*$  = equivalent Young's modulus,

510  $e_\alpha^v$  = microscopic fluid velocity,

511  $e_{oi}^k$  = initial void ratio of the  $k^{th}$  layer,

512  $e_{oi}^{avg}$  = initial void ratio of the entire sample considering all 10 Layers,

513  $e_r$  = coefficient of restitution,

514  $f_{bu}$  = static buoyancy force on the particle,

515  $f_{hyd}^p$  = total hydrodynamic force (including the static buoyancy force) on the particle  $p$ ,

516  $f_f$  = hydrodynamic forces on the particle without buoyancy force,

517  $f_g^p$  = gravitational force on the particle  $p$ ,

518  $f_j^c$  = force vector in  $j^{th}$  direction at contact  $c$ ,

519  $f^T$  = tangential contact force,

520  $f^N$  = normal contact force,

521  $f_o^{N,avg}$  = average normal contact force in a layer at the hydrostatic state,

- 522  $f_{\alpha}(x, t)$  = particle distribution function,
- 523  $f_{\alpha}(x, t^*)$  = particle distribution function after the collision of fluid particles,
- 524  $f_{\alpha}^{eq}(x, t)$  = equilibrium distribution function,
- 525  $G^*$  = equivalent shear modulus,
- 526  $I^p$  = moment of inertia of the particle  $p$ ,
- 527  $i_o$  = overall applied hydraulic gradient,
- 528  $i_{o,cr}$  = critical overall hydraulic gradient of the soil specimen,
- 529  $i_{hyd}$  = local hydraulic gradient in a layer,
- 530  $k_n$  = elastic constant for normal contact,
- 531  $k_t$  = elastic constant for tangential contact,
- 532  $M$  = Mach number,
- 533  $M_s$  = fraction of mechanically stable particles,
- 534  $m^p$  = mass of the particle  $p$ ,
- 535  $m^*$  = equivalent mass,
- 536  $N$  = lattice resolution,
- 537  $N_c$  = number of contacts,
- 538  $N_d$  = number of degrees of freedom,
- 539  $N_{ct}$  = number of constraints,
- 540  $N_c^p$  = number of contacts on particle  $p$ ,
- 541  $N_p$  = number of particles,
- 542  $N_p^{\geq 4}$  = number of particles with at least 4 or more contacts,
- 543  $n$  = overall porosity of the soil specimen,
- 544  $n_i^{c,p}$  = unit-normal vector from the particle' centroid to the contact location,
- 545  $n_L$  = number of layers,
- 546  $O_i$  = initial centroidal location of particle  $i$ ,

- 547  $O_j$  = initial centroidal location of particle  $j$ ,
- 548  $O'_j$  = displaced centroidal location of particle  $j$ ,
- 549  $R$  = constraint ratio for a three-dimensional particle system with only sliding resistance,
- 550  $R^*$  = equivalent radius,
- 551  $Re_p$  = Reynold's number of the particle,
- 552  $S$  = variance in the void ratios,
- 553  $S_i$  = slipping index,
- 554  $S_c$  = fraction of slipping contacts,
- 555  $T_f^p$  = fluid-particle interaction torque,
- 556  $T_j^c$  = interparticle contact torque due to tangential force,
- 557  $t$  = time,
- 558  $t^*$  = time after the collision,
- 559  $u$  = macroscopic fluid velocity,
- 560  $u_{max}$  = maximum velocity of the fluid flow in physical units,
- 561  $V$  = volume of the selected region or layer,
- 562  $V^p$  = volume of particle  $p$ ,
- 563  $v_d$  = superficial or discharge velocity of the fluid,
- 564  $\nu_f$  = kinematic viscosity of fluid,
- 565  $v_n^{rel}$  = normal component of the relative velocity of two spherical particles,
- 566  $v_t^{rel}$  = tangential component of the relative velocity of two spherical particles,
- 567  $v^p$  = translational velocity of the particle  $p$ ,
- 568  $w^p$  = angular velocity of the particle  $p$ ,
- 569  $\omega_\alpha$  = weighing factor for the microscopic fluid velocity,
- 570  $x^n$  = coordinate of the lattice cell,

- 571  $x_i^p$  = centre of mass of the particle,
- 572  $z$  = location of the particle,
- 573  $Z$  = coordination number,
- 574  $Z_{avg.}$  = average coordination number,
- 575  $\Delta x$  = lattice spacing,
- 576  $\rho_f$  = fluid density,
- 577  $\delta_n$  = normal overlap,
- 578  $\delta_t$  = tangential overlap,
- 579  $\Omega_\alpha$  = collision operator,
- 580  $\Omega_\alpha^{BGK}$  = collision operator of the BGK model,
- 581  $\Omega_\alpha^s$  = additional collision term for solid fraction,
- 582  $\varepsilon_s$  = solid fraction in the fluid cell volume,
- 583  $\tau$  = relaxation time,
- 584  $\mu_s$  = coefficient of sliding friction,
- 585  $\mu_f$  = dynamic viscosity of the fluid,
- 586  $\sigma'_{ij}$  = Cauchy effective stress tensor in the selected region,
- 587  $\sigma_{ij}^{p'}$  = average stress tensor within a particle  $p$ ,
- 588  $\sigma'_{zz}$  = Cauchy effective stresses of the particles in a layer in the fluid flow direction at any time,
- 589 and
- 590  $\sigma'_{zzo}$  = initial Cauchy effective stresses of the particles in a layer in the fluid flow direction.

713 **LIST OF TABLES**

714 **Table 1.** Fluid properties for simulating the single-particle falling into the fluid using the  
715 LBM-DEM approach (after Ten Cate et al. 2002).

716

717 **LIST OF FIGURES**

718 **Fig. 1.** Flowchart of the Lattice Boltzmann Method (LBM) combined with the Discrete  
719 Element Method (DEM).

720 **Fig. 2.** (a) Schematic representation of a single sphere falling into the fluid with a diameter  
721 ( $d_p$ ) = 15 mm; (b) the modelled particle in the fluid mesh using LBM-DEM; (c) comparison of  
722 the numerical and experimental results of particle position over time; (d) comparison of  
723 experimental and numerical results of particle velocity over time.

724 **Fig. 3.** (a) Particle size distribution of the sample selected for modelling in DEM; (b) three-  
725 dimensional sample modelled in DEM; (c) division of the sample into different layers with the  
726 mentioned layer numbers and initial void ratios ( $e_{oi}$ ); (d) a close-up view of the particles  
727 modelled in the fluid mesh using the LBM-DEM approach.

728 **Fig. 4.** Calibration of the soil specimen fluidisation model by comparing the flow curves  
729 obtained from the LBM-DEM and the documented experimental work.

730 **Fig. 5.** Evolution of the local hydraulic gradient ( $i_{hyd}$ ) and the normalised effective stresses  
731 ( $\sigma'_{zz}/\sigma'_{zz0}$ ).

732 **Fig. 6.** Evolution of broken contacts ( $B_R$ ) with the normalised effective stresses ( $\sigma'_{zz}/\sigma'_{zz0}$ ).

733 **Fig. 7.** Development of the fraction of mechanically stable particles ( $M_s$ ) with normalised  
734 effective stresses ( $\sigma'_{zz}/\sigma'_{zz0}$ ).

735 **Fig. 8.** Conceptual model showing the differences in the fabrics of particles with the same void  
736 ratios.

737 **Fig. 9.** Distributions of the coordination number ( $Z$ ) at the hydrostatic state and the onset of  
738 fluidisation of soil specimen.

739 **Fig. 10.** Development of the average coordination number ( $Z_{avg}$ ) with normalised effective  
740 stresses ( $\sigma'_{zz}/\sigma'_{zz0}$ ).

741 **Fig. 11.** Distribution of the slipping index ( $S_i$ ) of the selected Layer 10 with different local  
742 hydraulic gradients ( $i_{hyd}$ ).

743 **Fig. 12.** (a) Three-dimensional representation of the hydraulic gradient ( $i_{hyd}$ ), the normalised  
744 effective stresses ( $\sigma'_{zz}/\sigma'_{zz0}$ ), and the constraint ratio ( $R$ ); (b) projections of the three-  
745 dimensional plot of  $i_{hyd}$ ,  $\sigma'_{zz}/\sigma'_{zz0}$ , and  $R$ .

746 **Fig. A1.** Directions of the 19 (0-18) velocity vectors of the  $D3Q19$  discretisation scheme used  
747 in this study.

748 **Fig. A2.** (a) Rheological scheme and (b) schematic sketch of the Hertz-Mindlin contact model  
749 used in this study to simulate fluidisation of soil specimen.
