4 **Abstract**  
5

6       The effects of low-concentration Cr(VI) (0.4 mg/L) on the performance of a  
7 submerged membrane bioreactor (SMBR) in municipal wastewater treatment, as well as  
8 membrane fouling were investigated. Compared with the SMBR for control municipal  
9 wastewater, the SMBR for Cr(VI)-containing municipal wastewater had higher soluble  
10 microbial products (SMP) concentration with lower molecular weights, and smaller  
11 sludge particle sizes. Furthermore, low-concentration Cr(VI) induced membrane fouling,  
12 especially the irreversible membrane pore blocking, which markedly shortened the  
13 service life of membrane.

## 1 Introduction

2 Hexavalent chromium (Cr(VI)) is well known to impose adverse influence on the  
3 biological performance of the conventional activated sludge systems at different Cr(VI)  
4 concentrations, such as treatment efficiency and microbial composition (Stasinakis et al.  
5 2003; Stasinakis et al. 2003; Zhao et al. 2009; Vaiopoulou et al. 2012). In an activated  
6 sludge system, activated microorganisms are the bacteria and protozoa (mainly bacteria)  
7 used for the biodegradation of pollutants in biological process. The activated  
8 microorganisms and their biomass combined to form balls in the bioreactor, which are  
9 usually called sludge flocs. Cr(VI) can affect the particle size distribution of sludge  
10 flocs, although some conflicting results have been reported (Stasinakis et al. 2003).  
11 Madoni et al. and Stasinakis et al. found that high-concentration of Cr(VI) (5-400 mg/L)  
12 could induce acute reduction of oxygen uptake rate and decrease the maximum growth  
13 rate of activated sludge bacteria (Madoni et al. 1999; Stasinakis et al. 2003). Although  
14 the presence of Cr(VI) in the range of 1-20 mg/L only causes a small loss of organic  
15 substrate removal (Samaras et al. 2009), a significant inhibition of ammonia nitrogen  
16 removal can be observed at 0.5 mg/L Cr(VI) because autotrophic nitrifiers are more  
17 sensitive to Cr(VI) than heterotrophic microorganisms (Stasinakis et al. 2003).

18 A membrane bioreactor is the combination of a membrane process, such as  
19 microfiltration, with an activated sludge bioreactor. Compared with conventional  
20 activated sludge processes, a membrane bioreactor has many advantages, such as a  
21 smaller footprint, higher volumetric load, lower sludge production and better effluent  
22 quality. As submerged membrane bioreactor (SMBR) is one of the major type  
23 membrane bioreactors, its membrane module is submerged directly in the bioreactor and  
24 the filtration takes place in the bioreactor. In SMBR, Cr(VI) has a similar impact on the

1 microbial activities as in the conventional activated sludge systems. Cr(VI) can  
2 influence the sludge morphology, which further affects membrane filtration (Zhao et al.  
3 2009; Vaiopoulou and Gikas 2012). Membrane fouling variations at high Cr(VI)  
4 concentration have been reported (Zhao et al. 2009; Amiri et al. 2010).  
5 High-concentration Cr(VI) can significantly aggravate membrane fouling, as the  
6 microorganisms stimulated by Cr(VI) excrete a great amount of soluble microbial  
7 products (SMP) and extracellular polymeric substances (EPS) (Malamis et al. 2009;  
8 Samaras et al. 2009; Vaiopoulou and Gikas 2012).

9 Cr(VI) concentrations lower than 1 mg/L has been reported to reduce filamentous  
10 microorganisms in the conventional activated sludge system, which results in the  
11 appearance of pin-point flocs and free-dispersed bacteria (Stasinakis et al. 2003).  
12 Additionally, a poor settling property of the sludge is also observed at low-concentration  
13 Cr(VI) (lower than 1 mg/L). According to the investigations, the municipal wastewater  
14 in China contains low-concentration Cr(VI) (0.2-0.5 mg/L) (Chen et al. 2003; Cheng  
15 2003), and the yearly average Cr(VI) concentration remains at 0.4 mg/L (Stasinakis et al.  
16 2003; Zhao et al. 2009). Tons of Cr(VI) pollution is diluted with domestic wastewater  
17 and flowing into municipal wastewater treatment system in China. Additionally, the  
18 maximum permitted Cr(VI) concentration of industrial effluent in China is 0.5 mg/L  
19 (EPA 2002). Cr(VI) has become one of the major heavy metals in the municipal  
20 wastewater (Liu et al. 2005). Although the effect of low-concentration Cr(VI) (lower  
21 than 1 mg/L) on the pollution removal of SMBR has been reported by Zhao et. al.  
22 (2009), the effect of low-concentration Cr(VI) on membrane fouling is less studied. In  
23 view of the relationship between membrane fouling and microbial community,  
24 low-concentration Cr(VI) may have some special effects on SMBR performance (Xia et

1 al. 2010; Xia et al. 2012). To our best knowledge, the effect of low-concentration Cr(VI)  
2 (average value is 0.4 mg/L in municipal wastewater) on the performance and the  
3 membrane fouling in SMBR is unclear and needs further study.

4 This study aimed to investigate the effects of low-concentration Cr(VI) (0.4 mg/L)  
5 on the performance of a lab-scale SMBR feeding with Cr(VI)-bearing municipal  
6 wastewater (Cr(VI) concentration of 0.4 mg/L). The comparison study was made by  
7 using a control SMBR in treating non-Cr(VI) containing municipal wastewater. The  
8 performances of the SMBRs were evaluated in terms of the trans-membrane pressure  
9 (TMP), the production of SMP and EPS, and particle size distribution of sludge flocs. In  
10 addition, the contributions of membrane pore blocking, gel layer fouling and cake layer  
11 fouling to the total membrane fouling were examined using membrane fouling  
12 resistance analysis. The Fourier transform infrared analysis of foulants and the scanning  
13 electron microscopy-energy-dispersive X-ray analyzer analyses of membrane were also  
14 carried out to elucidate the effects of low-concentration Cr(VI) (0.4 mg/L) on the  
15 performance of the SMBR as well as the membrane fouling.

## 17 **Materials and methods**

### 18 *Experimental set-up and operation*

19 As Figure 1 showed, a lab-scale SMBR (SMBR-Cr(VI)) with a working volume of 3.0  
20 L was used. A polyvinylidene fluoride (PVDF) hollow fiber membrane module (pore  
21 size 0.4  $\mu\text{m}$ ) with a total surface area of 0.01  $\text{m}^2$  (Litree Company, China) was equipped  
22 in the reactor and the constant flux was set at 45  $\text{L}/(\text{m}^2\cdot\text{h})$  (LMH). Air (0.6  $\text{m}^3/\text{h}$ ) was  
23 supplied continuously through a perforated pipe under the membrane module. The  
24 influent was fed by a peristaltic pump controlled by a distributing pan. Filtration was

1 carried out in an intermittent suction mode with 10-min suction followed by 2-min  
2 release. Hydraulic retention time (HRT) and solids retention time (SRT) were kept at 8.0  
3 h and 30 days, respectively. Mixed liquor suspended solids (MLSS) were maintained at  
4  $3430 \pm 540$  mg/L during the operation. Considering the yearly average Cr(VI)  
5 concentration in municipal wastewater (Zhao et al. 2009), the concentration of Cr(VI)  
6 was maintained at 0.4 mg/L in SMBR-Cr(VI) using a stock solution (100 mg/L)  $K_2CrO_4$   
7 as Cr(VI) source. A same parallel SMBR (SMBR-Control) was operated at identical  
8 conditions without Cr(VI) addition.

### Figure 1

10 The inoculating sludge was drawn from the aerobic tank in the Qiyang wastewater  
11 treatment plant (Shanghai, China), which treats about 60000 m<sup>3</sup>/d of domestic  
12 wastewater using anaerobic-anoxic-oxic (A<sup>2</sup>/O) process. The reactors with inoculating  
13 sludge were firstly operated under the relevant conditions to achieve a steady state.  
14 Then they were equipped with the new membrane modules and worked as SMBRs to  
15 start the following experiments. When TMP reached 40 kPa, the membrane module was  
16 removed and washed with tap water to remove the cake layer (physical cleaning). The  
17 synthetic municipal wastewater was composed of 250 mg/L glucose, 250 mg/L corn  
18 starch, 57 mg/L  $NH_4Cl$ , 28 mg/L peptone, 52.8 mg/L  $KH_2PO_4$ , 9 mg/L  $MgSO_4 \cdot 7H_2O$ ,  
19 3.66 mg/L  $MnSO_4 \cdot H_2O$ , 0.55  $FeSO_4 \cdot 7H_2O$  and 8 mg/L  $CaCl_2$  (Miura et al. 2007; Xia et  
20 al. 2010).  $NaHCO_3$  with a concentration of 120 mg/L was used to maintain the pH at  
21 7.0-7.5. The average characteristics of influent and effluent water in both of the SMBRs  
22 are summarized in Table 1.

### Table 1

### 1 ***Extraction and measurement of EPS***

2 Extraction of SMP, loosely bound EPS and tightly bound EPS were performed  
3 according to a modified thermal extraction method (Jiang et al. 2013). A 40 mL  
4 activated sludge mixed liquor was first centrifuged (MILTIFUGE X1R, Thermo  
5 Electron Corporation, USA) at 6000 g for 5 minutes. Then the supernatant was filtered  
6 through a 0.45  $\mu\text{m}$  filter (SCAA-101, ANPEL, China) to get SMP. The remaining sludge  
7 was re-suspended in 40 mL of 0.9% NaCl solution, treated by ultrasound (DS510DT, 40  
8 kHz, 300W, Shangchao, China) for 8 minutes and then shaken at 150 rpm for 10  
9 minutes. After the final centrifugation at 8000 g for 10 minutes, the organic matter in  
10 the supernatant was regarded as the loosely bound EPS of the sludge. The sludge pellet  
11 left in centrifuge tube was re-suspended in 40 mL of 0.9% NaCl solution, and retreated  
12 by ultrasound for 4 minutes. The suspension was heated at 80 °C for 30 minutes and  
13 then centrifuged at 12000 g for 20 minutes. The supernatant was regarded as tightly  
14 bound EPS of the sludge. As SMP, loosely bound EPS and tightly bound EPS have been  
15 normalized as the concentration of carbohydrate and protein, they were measured by the  
16 phenol-sulfuric acid method and Branford method, respectively (Xia et al. 2012).  
17 Molecular weight (MW) distributions of SMP, loosely bound EPS and tightly bound  
18 EPS were studied by a gel filtration chromatography analyzer (LC-10ADVP, Shimadzu,  
19 Japan).

### 21 ***Resistance analysis***

22 When TMP reached 40 kPa and the membrane was considered to be fouled, the  
23 membrane resistance analysis was performed in triplicate every time. Based on the  
24 resistance-in-series model on the relationship between permeate flux and TMP (Lee et al.

1  
2  
3  
4 2001), the hydraulic resistance could be calculated according to the following equation:

$$R = R_m + R_p + R_c = \frac{\Delta P}{\mu J} \quad (1)$$

5  
6  
7  
8  
9  
10 Where  $R_m$  is the constant resistance of the clean membrane,  $R_p$  is the resistance due to  
11 pore blocking, and  $R_c$  is the fouling layer resistance caused by concentration  
12 polarization and cake layer.  $\Delta P$  is TMP,  $\mu$  is viscosity of the liquor, and  $J$  is permeate  
13 flux. The methods to measure the resistances of the membrane were as follow: (1)  $R_m$ :  
14 the flux and TMP of the new membrane module were measured using deionized water  
15 before the operation. (2)  $R$ : after the operation, the flux and TMP of the membrane  
16 module were measured in SMBR. (3)  $R_p+R_m$ : after removing the cake attached on the  
17 membrane surface by washing the membrane with tap water (physical clean method),  
18 the flux and TMP of the membrane module were measured using deionized water. (4)  $R_c$ :  
19  $R_m$  and  $R_p$  were subtracted from  $R$  to get  $R_c$ . From these values,  $R$ ,  $R_m$  and  $R_p+R_m$  of  
20 each SMBR could be obtained using Eq. (1).  
21  
22  
23  
24  
25  
26  
27

29  
30  
31  
32  
33  
34  
35  
36

### 37 *Additional analysis*

38  
39 Particle size distribution of sludge flocs was carried out using a focused beam  
40 reflectance measurement (Eyetechnology particle size and shape analyzer, Ankersmid,  
41 Holland). The organic substance information of foulants was determined with a Fourier  
42 transform infrared spectrometer (Nicolet 5700, Thermo Electron Corporation, USA).  
43  
44 Analyses of particle size distribution, MW and Fourier transform infrared were  
45 performed in triplicate. Inductively coupled plasma mass spectrometry (ICPMS 7700,  
46 Agilent, USA) was employed to measure Cr(VI) concentration. Measurements of  
47 chemical oxygen demand (COD), total nitrogen (TN), ammonia ( $\text{NH}_4^+\text{-N}$ ) and MLSS  
48 were performed according to Chinese National Environment Protection Agency (NEPA)  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1 standard methods (NEPA 1997). When TMP increased up to 40 kPa, membrane  
2 modules were used for both morphology and construction analysis by scanning electron  
3 microscopy (XL30, Philips, Netherlands) coupled with an energy-dispersive X-ray  
4 analyzer (Oxford Isis, UK).

## 6 **Results and discussion**

### 7 *Variations of TMP and SMP concentration*

8 The development rate of TMP is an important index to evaluate membrane filterability  
9 in SBR systems as it can directly reflect the extent of membrane fouling. TMP  
10 variations of SBR-Cr(VI) and SBR-Control are presented in Figure 2. The results  
11 indicated that low-concentration Cr(VI) (0.4 mg/L) had a crucial impact on the  
12 membrane fouling behavior, which was consistent with the report of Zhao et al.(2009).  
13 TMP variations of SBR-Cr(VI) were characterized by two-phase fouling phenomenon,  
14 namely a slow TMP rise followed by a rapid rise. Both SBR-Cr(VI) and  
15 SBR-Control initially displayed a similar trend and exhibited a fouling rate (dTMP/ dt)  
16 of 1.33 kPa/d at the beginning of 30 days. TMP increased slowly during this period.  
17 However, a fast TMP jump (7.51 kPa/d) occurred at 32<sup>th</sup> day in the SBR-Cr(VI),  
18 which gave the signal of severe membrane fouling. TMP jump might result from sudden  
19 changes of the cake layer structure. A recent investigation confirmed that TMP jump  
20 was closely related to a sudden increase of the SMP concentration at the bottom of cake  
21 layer (Hwang et al. 2008). In addition, SMP were released from bacterial to form a  
22 protective barrier for preventing harmful effects of heavy metals (Pal et al. 2008;  
23 Samaras et al. 2009). After physical cleaning, TMP in SBR-Cr(VI) and  
24 SBR-Control decreased about 21 and 34 kPa, respectively, indicating that the pore

1 blocking in SMBR-Cr(VI) was more severe than that in MBR-Control. Compared with  
2 SMBR-Control, the higher fouling rate (about 7.21 kPa/d) in SMBR-Cr(VI) further  
3 confirmed the severe pore blocking in SMBR-Cr(VI). Thus, low-concentration Cr(VI)  
4 (0.4 mg/L) could cause severe membrane fouling through the cake layer structure  
5 change, which not only enhanced pore blocking, but also increased the concentration of  
6 SMP.

### 7 **Figure 2**

8 SMP in MBR also plays a significant role in membrane fouling (Meng et al. 2009;  
9 Tian et al. 2011) and Cr(VI) removal (Kilic et al. 2008). During filtration, SMP from the  
10 bulk attaches to the membrane surface, blocks membrane pores, and forms a gel layer.  
11 Figure 2 showed the variations of SMP concentration in SMBR-Cr(VI) and  
12 SMBR-Control. The SMP concentration increased gradually along with the  
13 development of TMP in two SMBRs, which was consistent with the fact that both  
14 composition and concentration of organic matter in SMP has great impact on membrane  
15 fouling (Le-Clech et al. 2006). Figure 3 revealed that protein was the main component  
16 of SMP, and the protein concentration of SMP in SMBR-Cr(VI) was higher than that in  
17 SMBR-Control. The protein concentration with high-concentration (over 50 mg/L)  
18 Cr(III), which was considered as the toxic substance for bacteria, was about 12.69 mg/L  
19 (Malamis et al. 2009). SMBR-Cr(VI) had a similar protein concentration, indicating that  
20 low-concentration Cr(VI) (0.4 mg/L) could also be toxic to bacteria. As can be seen,  
21 once Cr(VI) in the influent of SMBR promoted the release of protein by  
22 microorganisms in the system. Therefore, low-concentration Cr(VI) (0.4 mg/L) can  
23 increase the protein concentration of SMP, which can further arouse a TMP jump and  
24 aggravate severe membrane fouling.

**Figure 3*****Particle size distributions of sludge particles***

The particle size distributions of the sludge particles in SMBR-Cr(VI) and SMBR-Control are presented in Figure 4. The sludge particles of SMBR-Cr(VI) had a narrower range profile of size distribution, and the mean particle size of SMBR-Cr(VI) was smaller than that of SMBR-Control. Statistical results of the sludge particle distributions are summarized in Table 2. In SMBR-Cr(VI), about 75% of the particles was distributed in the size range of 10-50  $\mu\text{m}$ , and 22% of particles was in the size range from 0 to 10  $\mu\text{m}$ . However, in SMBR-Control, over 50% sludge particles fell between the particle range of 50-200  $\mu\text{m}$  with few particles in the range of 0 to 10  $\mu\text{m}$ .

**Figure 4****Table 2**

The results indicated that low-concentration Cr(VI) (0.4 mg/L) would cause smaller particles distributed in the 0-50 $\mu\text{m}$  range. The results might be due to the reduction of the filamentous microorganism concentration and the significant increase of planktonic bacteria population in the mixed liquor. Moreover, EPS was reported to bond Cr(VI) more easily than planktonic bacteria (Pal and Paul 2008; Vaiopoulou and Gikas 2012). Thus, the formation of larger sludge particles was inhibited due to the absence of EPS for the combination of bacteria and EPS. Hence, low-concentration Cr(VI) (0.4 mg/L) could inhibit the formation of large particles, because of its influence on microorganism community structure and EPS. In addition, small particles generally have a strong tendency to deposit on the membrane surface for cake layer formation and penetrate into membrane pores, further leading to pore blocking. Thus, the results are in

1  
2  
3  
4 1 line with the explanation of severe membrane fouling observed in SMBR-Cr(VI)  
5  
6 2 through the variations of TMP and SMP concentration.  
7  
8  
9 3

#### 4 *MW distributions of SMP and EPS*

5 As a significant factor indicating the performance and membrane fouling of SMBR  
6 (Wang et al. 2009), the MW distributions of SMP and EPS in two SMBRs were  
7 investigated with gel filtration chromatography (Figure 5). SMBR-Cr(VI) had lower  
8 MW molecules of SMP, while the MW molecules of loosely bound EPS and tightly  
9 bound EPS in two SMBRs were almost similar. Low-concentration Cr(VI) (0.4 mg/L)  
10 could affect microbial metabolism, synthesis of biomolecules, and the microorganisms  
11 in activated sludge (Vaiopoulou and Gikas 2012), which play key roles in the release  
12 and structure of EPS (Lapidou et al. 2002). Recent studies also showed that a possible  
13 reduction mechanism of Cr(VI) toxic effects might relate to the presence of soluble EPS  
14 in activated sludge (Kilic and Donmez 2008; Pal and Paul 2008; Parvathi et al. 2008). In  
15 this study, the variations MW of SMP, loosely bound EPS and tightly bound EPS in two  
16 SMBRs were different as above mentioned, which had never reported. This observation  
17 indicated that low-concentration Cr(VI) (0.4 mg/L) in SMBR mainly affected the MW  
18 distribution of SMP by causing the release of more lower MW molecules. There was no  
19 effect on loosely bound EPS or tightly bound EPS. Additionally, a big proportion of low  
20 MWs could lead to a severe membrane fouling in SMBR-Cr(VI) through pore blocking.

#### 21 **Figure 5**

#### 22 23 *Fourier transform infrared analysis of foulants*

24 The Fourier transform infrared spectra of the foulants on the membranes in two SMBRs

1 are presented in Figure 6. The spectra showed a broad region of adsorption around a  
2 peak at  $3434.5\text{ cm}^{-1}$ , which was due to the stretch of the O-H bond in hydroxyl  
3 functional groups, as well as a sharp peak at  $2930.6\text{ cm}^{-1}$ , which was attributed to the  
4 stretch of the C-H bonds (Maruyama et al. 2001). Furthermore, there was a peak at  
5  $1635.2\text{ cm}^{-1}$  which was unique to the protein secondary structure, called amides I,  
6 indicating the presence of proteins in membrane fouling. A broad peak at  $1047.6\text{ cm}^{-1}$   
7 was due to polysaccharides or polysaccharide-like substances (Meng et al. 2007).  
8 However, there were some differences in the major components between the foulants of  
9 two SMBRs. Compared with foulants in SMBR-Control, the lack of  $1544.7\text{ cm}^{-1}$  peak in  
10 SMBR-Cr(VI), which was unique to the amides II protein secondary structure (Meng et  
11 al. 2007), indicated the absence of some proteins in the foulants as a result of  
12 low-concentration Cr(VI) (0.4 mg/L).

### Figure 6

#### *Analysis of membrane fouling resistance*

16 Total membrane resistance ( $R$ ) includes intrinsic membrane resistance ( $R_m$ ), pore  
17 blocking resistance ( $R_p$ ) and fouling layer resistance ( $R_c$ ) (Lee et al. 2001). Although  
18 several papers had studied on the effect of chromium on the membrane fouling, the  
19 conclusions were contradictory (Dialynas et al. 2009; Zhao et al. 2009). Besides, only  
20 few reports discussed the influence of Cr(VI) on each fouling resistance and the  
21 membrane fouling mechanism. As shown in Table 3, total membrane resistance and  
22 membrane layer resistance of SMBR-Cr(VI) were 2.05 and 1.91 times of those of  
23 SMBR-Control, respectively. Moreover, the fouling layer was the main component  
24 contributing to the total membrane resistance in SMBR-Cr(VI), illustrating that

1 SMBR-Cr(VI) suffered from severe membrane fouling because of the cake layer fouling.  
2 According to the recent studies, high-concentration SMP could cause severe cake layer  
3 fouling. The deposited biopolymers could promote easier and faster bacterial adhesion,  
4 and SMP could trap particles more tightly on the membrane (Chu et al. 2005; Meng et al.  
5 2009). The TMP jump (As shown in Section “*Variations of TMP and SMP*  
6 *concentration*”) also supported the hypothesis that the severe membrane fouling in  
7 SMBR-Cr(VI) was due to the high-concentration SMP around the cake layer. The TMP  
8 variations after physical cleaning indicated severe pore blocking in SMBR-Cr(VI).

### Table 3

9  
10 As shown in Table 3,  $R_p$  in SMBR-Cr(VI) was 8.94 times higher than that of  
11 SMBR-Control. Table 3 shows the resistance distributions of the membrane filtration in  
12 SMBR-Cr(VI) and SMBR-Control. The percentage of  $R_p$  to  $R$  in SMBR-Cr(VI) was  
13 about 10.85%, which is 4.84 times of that in SMBR-Control (2.24%). All these results  
14 indicated that low-concentration Cr(VI) (0.4 mg/L) induced severe membrane pore  
15 blocking. The toxicity of Cr(VI) could cause the appearance of pin-point flocs and  
16 planktonic microorganisms and some damage to the cells. Thus, the small size organic  
17 matter could block the membrane pores, as suggested by Zhao et al. (2009). According  
18 to some previous conclusions (Lyko et al. 2008; Meng et al. 2009; Shon et al. 2009), the  
19 high-concentration and low-MW SMP could lead to severe membrane pore blocking  
20 and membrane filtration reduction. Since membrane pore blocking is the initial phase of  
21 particulate fouling and irreversible fouling, and is considered to be the most severe  
22 fouling (Meng et al. 2007; Guo et al. 2012), the resistance results indicated that  
23 low-concentration Cr(VI) (0.4 mg/L) could complicate the irreversible membrane  
24 fouling and shorten the service life of membrane module.

1

## 2 *Membrane morphology and construction*

3 Scanning electron microscopy images (Figure 7) were taken to identify the morphology  
4 of membrane fouling on the membrane surface. The membrane surface of SMBR-Cr(VI)  
5 was covered by a cake layer with a thickness around 8.62  $\mu\text{m}$ . Nevertheless, a thinner  
6 cake layer (4.35  $\mu\text{m}$ ) was covered on the membrane surface of SMBR-Control. These  
7 data demonstrated that low-concentration Cr(VI) (0.4 mg/L) had a crucial effect on  
8 cake-layer fouling by increasing of cake layer thickness.

9

### Figure 7

10

11 Element analysis of the surface cake layer was further performed to determine the  
12 chemical components of the layer. The elements of C, O, N, Na, K, Mg, Ca, Si and Cr  
13 were detected in the cake layer of SMBR-Cr(VI) and SMBR-Control (Table 4).  
14 Although the relative contents of Mg, Ca and Si in the layer were small, these elements  
15 contributed significantly to the cake layer formation. Mg, Ca and Si could bridge the  
16 deposited cells and biopolymers and then formed a dense cake layer when they pass  
17 through the membranes (Huang et al. 1998; Meng et al. 2007). Additionally, the  
18 contents of Ca decreased from 8.26% to 2.60%, but there was little variation of those of  
19 Mg and Si. The decrease of Ca content in cake layer indicated that low-concentration  
20 Cr(VI) (0.4 mg/L) might promote the bridging and flocculation between  $\text{Ca}^{2+}$  and the  
21 biopolymers, which will aggravate membrane fouling. Large amounts of carbon,  
22 representing organic foulants, were observed in the cake layer of SMBR-Cr(VI). The  
23 organic foulants coupled with the inorganic precipitation could accelerate the cake layer  
24 formation, which resulted in severe pore blocking and shortened the lifespan of

1 membrane module. The large amount of carbon was also consistent with the result that  
2 low-concentration Cr(VI) (0.4 mg/L) induced an increase in SMP(Seen in Figure 2 and  
3 Figure 3). It was also found that the relative content of Cr in foulants was small,  
4 because Cr(VI) concentration was low.

5 **Table 4**

## 6 **Conclusions**

7 The performance of SMBR and membrane fouling were evaluated using municipal  
8 wastewater with low-concentration Cr(VI) (0.4 mg/L). That concentration had no  
9 apparent side effects on treatment efficiency but led to the mean size decrease of the  
10 sludge particles. Low-concentration Cr(VI) (0.4 mg/L) increased SMP concentration  
11 and reduced mean MW molecules. There was no such tendency for either loosely bound  
12 EPS or tightly bound EPS. All analyses on contributing factors towards membrane  
13 fouling showed that low-concentration Cr(VI) (0.4 mg/L) induced severe cake layer  
14 fouling. Moreover, it could aggravate the membrane pore blocking and the irreversible  
15 membrane fouling, thereby shortening the service life of membrane module.

## 16 **Acknowledgements**

17 The authors sincerely thank the supports from the National Science & Technology Pillar  
18 Program (2013BAD21B03), the Fundamental Research Funds for the Central  
19 Universities, Shanghai Shuguang Tracking Program (10GG12), and 1<sup>st</sup> World

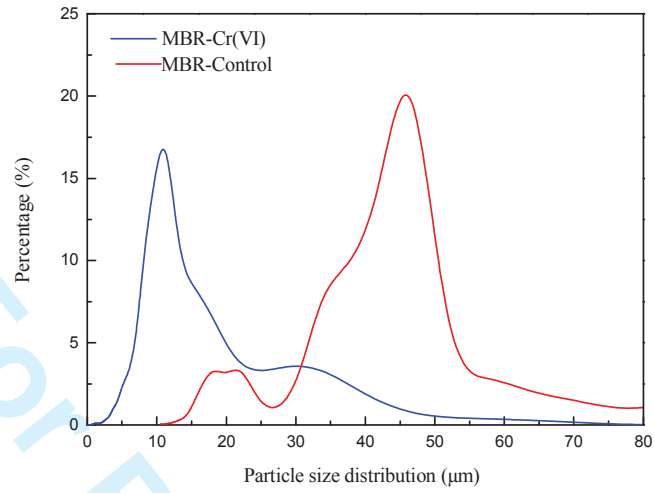

**Figure 1** A schematic of submerged membrane bioreactor (SMBR) (SMBR-Cr(VI) with low-concentration Cr(VI) (0.4 mg/L) and SMBR-Control without Cr(VI) were run at the same condition in two similar reactors, respectively.)

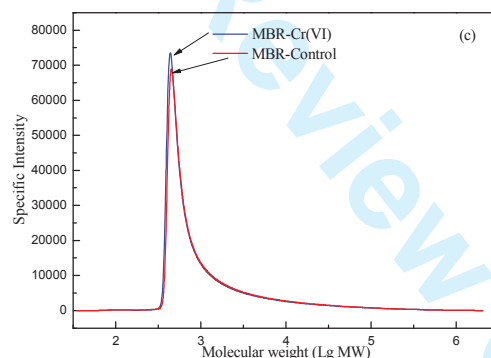

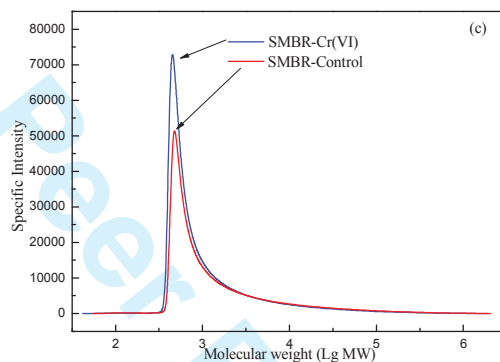

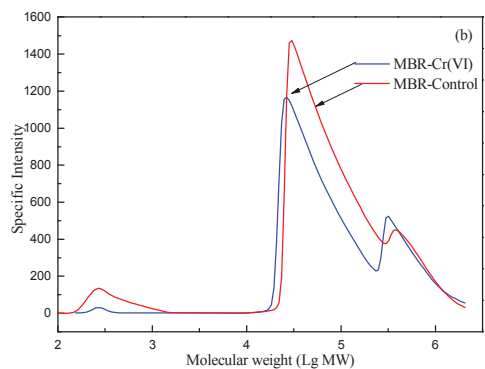

**Figure 2** Variations of the trans-membrane pressure (TMP) and soluble microbial products (SMP) concentrations in SMBR-Cr(VI) and SMBR-Control (SMBR-Cr(VI) had a TMP jump at day 32<sup>th</sup>. The resistance analysis was carried out at day 35<sup>th</sup>, 48<sup>th</sup>, 60<sup>th</sup>, 70<sup>th</sup> for SMBR-Cr(VI) and day 46<sup>th</sup>, 75<sup>th</sup> for SMBR-Control, when the TMP reached 40 kPa. The physical cleaning was performed at day 38<sup>th</sup>, 48<sup>th</sup>, 65<sup>th</sup> for SMBR-Cr(VI) and at day 47<sup>th</sup> for SMBR-Control. Rapid SMP increase occurred during 25<sup>th</sup> to 30<sup>th</sup> in SMBR-Cr(VI).)

**Figure 3** Variations of carbohydrate and protein concentrations of soluble microbial products (SMP) in SMBR-Cr(VI) and SMBR-Control (Because SMP was excreted by the microorganisms in sludge, its concentration depended on the microorganism behaviors to the surrounding condition, such as toxicity shock. The physical and chemical clean was done outside two SMBRs. It caused no effects on the microorganism behaviors. Thus, the differences between the SMPs in the two SMBRs were due to low-concentration Cr(VI) (0.4 mg/L).)
