ABSTRACT

A simple and novel method to synthesize iron and aluminium-doped titanium dioxide (TiO₂) was investigated. Titanium tetrachloride (TiCl₄) was used as a coagulant to remove organic matter from wastewater. The settled floc (sludge) was dewatered and incinerated at 600 °C after TiCl₄ flocculation. The resultant by-product from the waste sludge was valuable TiO₂. TiCl₄ coagulant was added with FeCl₃ and Al₂(SO₄)₃ coagulants to dope iron and aluminium on TiO₂ in a flocculation process. The effect of iron and aluminium on TiO₂ was investigated in terms of scanning electron microscopy/energy dispersive X-ray (SEM/EDX), X-ray diffraction (XRD), optical absorbance and photocatalytic activity. The majority of Fe/ and Al/TiO₂ particles were found to be less than 1 μm size formed by 0.1 μm agglomerates using SEM analysis. Fe/TiO₂ included Ti, O, C, P and Fe elements and Al/TiO₂ consisted of Ti, O, C, P and Al elements as confirmed by EDX results. Remaining organic carbon from the settled organic matter was the source of C atom in TiO₂ whereas the P atom in TiO₂ came from phosphorus nutrient present in wastewater. As iron concentration increased, the atomic percentage of the iron element in Fe/TiO₂ increased significantly from 0.27 at% (low iron concentration) to 9.83 at% (high iron concentration). However, the atomic percentage of the Al element in Al/TiO₂ increased slightly from 0.1 at% (low aluminium concentration) to 0.46 at% (high aluminium concentration) with an increase in aluminium concentration. The Fe/TiO₂ exhibited the majority of anatase phase. At higher iron concentration, hematite (Fe₂O₃) was found. The Al/TiO₂ showed anatase phase only at different aluminium concentrations. The majority of acetaldehyde with Fe/ and Al/TiO₂ was significantly removed under UV irradiation within 60 minutes. However, at higher iron concentration, acetaldehyde removal decreased by almost 50%. Under visible light irradiation, the photo-decomposition of acetaldehyde using the Fe/ and Al/TiO₂ was marginal.

Keywords: Titanium oxide, iron doping, aluminium doping, wastewater, flocculation
INTRODUCTION

Sludge disposal is one of the major problems in wastewater treatment plants. Chemical treatment by flocculation produces a large amount of sludge (settled floc) and this is generally disposed in landfill – a solution which is becoming less acceptable in view of the growing community resistance to finding new disposal sites or expanding existing ones. Treatment methods for efficient sludge recycling are therefore needed.

A novel flocculation system for producing functional TiO$_2$ using wastewater was investigated to reduce a large amount of sludge [1]. Titanium tetrachloride (TiCl$_4$) was used instead of most commonly used salts of iron (FeCl$_3$) and aluminium (Al$_2$(SO$_4$)$_3$) as an alternative coagulant to remove particulate and dissolved organic matter from wastewater in sewage treatment plants (STPs). Titanium tetrachloride (TiCl$_4$) successfully removed organic matter at the same level as Fe and Al salts. Ti sludge settled faster which made the subsequent separation process easy. After flocculation with titanium salt, the settled floc was incinerated to produce functional titanium dioxide (TiO$_2$) which resembled to commercial TiO$_2$. Thus, the use of Ti salt was more efficient than using Fe or Al salts and recovered a by-product of functional TiO$_2$ of 446.5 kg/day from a medium size STP of 25 mega liters per day. Ti salt costs are fairly cheap similar to Al and Fe salts. This process is efficient, economical and produces a viable commercial product not only in terms of removal of organic matter, but also in sludge reduction and wastewater reuse. The amount of TiO$_2$ recovered from this process fulfills the demand of TiO$_2$ as required in TiO$_2$ photo-catalysis during environmental
applications by photo-catalysis and hydrogen generation by photocatalytic water-splitting.

TiO₂ is the most widely used metal oxide for environmental applications, cosmetics, paints, electronic paper, and solar cells [2-4]. Current research has sought to improve the photo-catalytic properties of TiO₂ with metals or oxides [5-8]. Transition metals (Fe, Al, Ni, Cr, Co, W and V), metal oxides (Fe₂O₃), Cr₂O₃, CoO₂, MgO + CaO and SiO₂), transition metal ceramics (WO₃, MoO₃, Nb₂O₅, SnO₂ and ZnO) and anionic compounds (C, N and S) have been used to coat and dope TiO₂ to improve its applicability [9]. Among them, transitional metal and rare earth metal ions have been widely tried as dopants to improve the photocatalytic efficiency of TiO₂. As metal ions are doped into TiO₂, impurity energy levels in the band gap are formed. This leads to alteration of electron hole recombination. Transitional metals are either deposited or doped on the TiO₂ surfaces as metallic nanoparticles or the metals are doped as ionic dopants. A common method consists of doping in TiO₂ with transition metal cations while maintaining a good control of the primary particle size to achieve nanoscale configurations of the catalysts. The doping elements have usually been Fe, Al, Cr, V, Nb, Sb, Sn, P, and Si [10].

Iron has been used to dope TiO₂ and its photocatalytic activity was superior than the commercial Degussa P-25 under visible light irradiation [11]. Teoh et al. [12] also reported that Fe-doped TiO₂ was found to have very high photocatalytic activity under visible light irradiation than Degussa P-25. Fe³⁺ cations acted as shallow traps in the TiO₂ lattice. Optimum photocatalytic properties were achieved upon doping at a
relatively weak level. This was closely related to the dynamics of the recombination process which was linked to the distance between dopant cations in the TiO$_2$ lattice [13]. Fe ions trapped not only electrons but also holes, which leads to increase of photoactivity [14]. The maximum photoactivity appeared with 0.5 wt% of Fe$^{3+}$ due to decrease in the density of the surface active centers [15]. The added Fe atoms dissolved in TiO$_2$ phase was found to have a rutile structure with average grain size less than 10 nm. Fe-doped powder had a higher absorption threshold in the range of 427-496 nm than the commercial P-25 powder (406 nm). The colour changed from white to bright yellow in Fe-doped powder. When Fe content exceeded 4.6 wt%, the optical property of Fe/TiO$_2$ absorbed visible light.

Aluminium doping has been used on TiO$_2$ for a potential application in thermal shock due to its stable thermal expansion coefficient and physical property [16]. Al$_2$O$_3$ and Al$_2$TiO$_5$ were observed at AlCl$_3$/TiCl$_4$ ratios higher than 1.1 at 1400 ºC [17]. They discovered a formation of new structure connected with Al-O-Ti framework. For Al/TiO$_2$, the anatase structure was stable after calcination at 800 ºC, while pure TiO$_2$ was easily transferred to the rutile phase after calcination above 700 ºC. The optical property of Al/TiO$_2$ prepared by a thermal plasma method responded visible light [18]. They also found that the size of synthesized powder decreased with increase in the amount of Al because Al species inhibited the particle growth. Al/TiO$_2$ has been applied to gas sensor, which needs high conductivity of TiO$_2$ [19]. It has been reported that the conductivity of the Al-doped TiO$_2$ is higher than pure TiO$_2$ in a temperature ranging from 600 ºC to 900 ºC.
In this study, a novel and simple method to produce Fe/ and Al/TiO₂ was developed. The effect of iron and aluminium on TiO₂ was investigated in terms of various iron and aluminium concentrations. TiCl₄ as a novel coagulant was co-flocculated with FeCl₃ and Al₂(SO₄)₃ as conventional coagulants. This novel method produced Fe/TiO₂ and Al/TiO₂. Fe/TiO₂ and Al/TiO₂ were characterized in terms of structural, chemical and photo-electronic properties (X-ray diffraction (XRD), optical absorbance, scanning electron microscopy/energy dispersive X-ray (SEM/EDX) and photocatalytic activity).

**Experimental**

**Organic removal through TiCl₄ flocculation in synthetic wastewater**

Co-flocculation was carried out with TiCl₄ coagulant which was associated with different doses of FeCl₃ (0.083 mg/L – 83 mg/L) and Al₂(SO₄)₃ (0.038 mg/L – 38 mg/L) in synthetic wastewater. The composition of the synthetic wastewater is presented in Table 1 [20]. This synthetic wastewater represents effluent organic matter generally found in biologically-treated sewage effluent. Tannic acid, peptone, sodium lignin sulfochrome, sodium lauryl sulfate and arabic acid represent the larger molecular weight portion, while peptone, beef extract and humic acid comprise the organic matters of lower molecular weight [21]. The samples were stirred rapidly for 1 minute at 100 rpm, followed by 20 minutes of slow mixing at 30 rpm, and 30 minutes of settling. Organic matter was measured using a Dohrmann Phoenix 8000 UV-persulphate TOC analyzer equipped with an autosampler. All samples were filtered through 0.45 µm membrane prior to organic measurement.

Characterization of TiO₂

The visual microscopy was used to measure the shape and aggregated particle size of TiO₂. Scanning electron microscopy/energy dispersive X-ray (SEM/EDX, Rigaku, Japan) was used. XRD images (Rigaku, Japan) of anatase and rutile TiO₂ photocatalysts to identify the particle structure was investigated. All the XRD patterns were analyzed with MDI Jade 5.0 (Materials Data Inc., USA). UV-VIS-NIR spectrophotometer (Cary
500 Scan, Varian, USA) was used to identify the absorbance range and the band gap of TiO$_2$ was calculated.

The photocatalytic activity test of TiO$_2$ was investigated under irradiation of UV (Sankyo, F10T8BLB, three 10 W lamps) and visible light (Kumbo, FL10D, three 10W lamps) using the method of photodecomposition of gaseous acetaldehyde. The concentration of acetaldehyde was measured by gas chromatography (Youngin, M600D, Korea).

RESULTS AND DISCUSSION

Dissolved Organic Carbon removal by TiCl$_4$ flocculation

Figure 1 shows the removal of dissolved organic carbon (DOC) after TiCl$_4$ flocculation at different TiCl$_4$ concentrations using synthetic wastewater. The concentration of the TiCl$_4$ coagulants was varied from 2.50 to 13.0 Ti-mg/L. The removal of organic matter was approximately 70% at 8.5 Ti-mg/L of the optimum concentration. The comparison of DOC removal in terms of different coagulants such as Fe- and Al-salt coagulants can be found elsewhere [1]. Shon et al. [1] reported that the size of the settled floc after TiCl$_4$ flocculation was 47.5 μm, which led to faster settling.
Figure 1 DOC removal by TiCl$_4$ flocculation in synthetic wastewater (initial concentration of DOC = 10.05 mg/L; initial pH = 7.3)

To investigate the effect of co-flocculation by Fe- and Al-salt coagulants with TiCl$_4$ flocculation, FeCl$_3$ and Al$_2$(SO$_4$)$_3$ coagulants in the TiCl$_4$ flocculation at the optimum concentration (8.5 Ti-mg/L) in synthetic wastewater were added in the range of 0.083 Fe-mg/L – 83 Fe-mg/L and 0.038 Al-mg/L – 38 Al-mg/L, respectively. The detailed sample information is shown in Table 2. Each sample is named as shown in Table 2 hereafter in this paper.

**SEM/EDX results**

In order to investigate the effect of Fe and Al atoms on TiO$_2$ produced from the settled floc through Ti-salt flocculation using Fe- and Al-salt coagulants, the settled floc was calcined at 600 °C. This led to mineralization of all the organic and water compounds. Fe- and Al-doped TiO$_2$ were prepared and characterized as below.

Figure 2 shows SEM images and EDX spectra of Fe/ and Al/TiO$_2$ powders at different concentrations of Fe and Al-salts. The samples consisted of particles of various size, shape and dimension. The majority of these particles were found to be less than 1 μm. Further investigations indicated these particles were constituted by agglomerates of a particle (approximately 0.1 μm size). The SEM image of 83-Fe/TiO$_2$ particles showed...
irregular in shape and dimensions compared to other particles. Navio et al. [22] reported that Fe/Ti samples (less than 3 wt% Fe) by a sol-gel method presented deposits irregular in shape and dimensions, while the Fe/Ti samples (more than 5 wt% Fe) showed deposits homogeneous in shape and dimensions. In the case of Al/TiO₂, Lee et al. [18] reported that the size of TiO₂ particles decreased with the increase in Al dopant due to the suppression of particle growth by an introduction of Al atoms into TiO₂ crystal.

EDX analysis was performed to determine the presence of different elements in Fe/ and Al/TiO₂ (Figure 2). Different elements were uniformly spread inside and on the Fe/ and Al/TiO₂ using the EDX mapping technique. The homogeneous distribution of Al and Fe into TiO₂ shows the absence of Al₂O₃ and Fe₂O₃ particles. Fe, Ti, O, C and P were the main constitutive elements of Fe/TiO₂ whereas Al, Ti, O, C and P were in case of Al/TiO₂. The intensity of the Fe element increased with an increase in Fe concentration. However, the intensity of the Al element remained constant with the increase in Al concentration.
Tables 3 and 4 show atomic fraction of different elements in Fe/ and Al/TiO₂, respectively. Here, the C atom came from remaining organic carbon of the settled organic matter and phosphorus nutrient present in wastewater was the source of P atom. It is widely accepted that flocculation removes the majority of organic matter and phosphorus [23]. Various trace elements (Si, Fe, Al, V, Ca, Na, Cr, Cl, S, Ni and Br)
were found in TiO₂ retrieved from flocculation sludge. Shon et al. [1] reported that most of the C and P atoms were doped as a substitute site for an O atom, while the Fe and Al atoms would be doped as a substitute site for a Ti atom [24]. As Fe concentration increased, the atomic percentage of the Fe element in Fe/TiO₂ increased significantly from 0.27% (0.083-Fe/Ti) TiO₂ to 9.83% (83-Fe/TiO₂). However, the atomic percentage of the Al element in Al/TiO₂ slightly increased from 0.1% (0.038-Al/TiO₂) to 0.46% (38-Al/TiO₂) with an increase in Al concentration. This indicated that co-flocculation of FeCl₃ and Al₂(SO₄)₃ with TiCl₄ was more favorable with the FeCl₃ coagulant than with the Al₂(SO₄)₃. Figure 3 shows the linear regression of Fe and Al atomic fraction inside and on TiO₂ versus different Fe and Al concentrations in wastewater. The results suggest that Fe salt flocculation with Ti salt is more favorable to the settled floc.

XRD results

The Fe/ and Al/TiO₂ powder calcined at 600 °C were investigated in terms of XRD to identify the particle size and structure (Figure 4). The Fe/TiO₂ exhibited the majority of patterns assigned to the anatase phase. At relatively lower iron concentration in TiO₂ (0.083-Fe/TiO₂ – 8.3-Fe/TiO₂), a crystalline phase containing Fe atoms (α-Fe₂O₃, Fe₂TiO₅, etc.) was not observed. This may be due to low concentration of Fe₂O₃ and/or a substitute site (Fe³⁺) for a Ti⁴⁺ ion in TiO₂. However, at 83-Fe/TiO₂, hematite (α-Fe₂O₃) was found. This may be due to higher iron concentration. In this study, all the Fe/TiO₂ consisted of the anatase phase. In contrast, Hung et al. [25] reported that the presence of iron may catalyze the transformation of anatase to rutile. The radius of Fe³⁺
(0.64 Å) is similar to that of Ti$^{4+}$ (0.68 Å). Owing to its smaller size the Fe$^{3+}$ ions present on the surface of TiO$_2$ iron compact the TiO$_2$. The iron in the matrix of TiO$_2$ is a favourable process and easily forms the rutile phase due to open channels. The crystalline size of Fe/TiO$_2$ at different iron concentrations was investigated by Scherrer’s formula [26]. As iron concentration in TiO$_2$ increased, the anatase phase intensity decreased. This suggests that the Fe species inhibited a crystalline growth (Lee et al., 2004). The crystallite sizes of the Fe/TiO$_2$ were approximately 11 nm (0.083-Fe/TiO$_2$) and 5 nm (83-Fe/TiO$_2$).

XRD analysis of Al/TiO$_2$ also demonstrates the majority of the anatase phase (Figure 4). A crystalline phase containing Al atoms ($\alpha$-Al$_2$O$_3$, Al$_2$TiO$_5$, etc.) was not observed even at higher Al concentrations. This may be due to low concentration of Al$_2$O$_3$ and/or a substitute site (Al$^{3+}$) for a Ti$^{4+}$ ion [27]. Since ionic radius for Al and Ti is also similar (0.68 Å for Al$^{3+}$), Al can occupy a regular cation position, forming a substitutional solid solution. In addition, Al species dissolved well into the TiO$_2$ crystal [18]. As discussed above in EDX results, Al/TiO$_2$ has low atomic percentages in the range from 0.1 at% to 0.46 at% compared with Fe/TiO$_2$ (from 0.27 at% to 9.83 at%). The crystalline size of Al/TiO$_2$ at different Al concentrations was investigated by Scherrer’s formula. The intensity of the anatase phase decreased with an increase in Al concentration in TiO$_2$. This suggests that the Al species also inhibited a crystalline growth as did Fe species. The crystallite sizes of the Al/TiO$_2$ were approximately 11 nm (0.038-Al/TiO$_2$) and 8 nm (38-Al/TiO$_2$).
Figure 4 XRD patterns of the Fe and Al-doped TiO$_2$ particles produced from calcination of the settled floc at 600 °C a) after TiCl$_4$ and FeCl$_3$ and b) after TiCl$_4$ and Al$_2$(SO$_4$)$_3$ flocculation (A: anatase phase (TiO$_2$); H: hematite (α-Fe$_2$O$_3$))
The optical properties of Fe/ and Al/TiO₂ were investigated using the ultra violet–visible-near infrared (UV-VIS-NIR) spectrophotometer (Figure 5). Generally, the absorption band of Ti⁴⁺ tetrahedral symmetry appears around 300 nm. The absorption bands from 8.3-Fe/TiO₂ concentration of iron ions were shifted significantly up to 500 nm of wavelength. Hung et al. [25] reported that the optimum doping amount of iron ions was 0.005 mol%. UV-Vis diffuse reflectance spectra of Fe/TiO₂ showed an increase in absorbency in the visible light region with the increase in iron ions doping concentration. It was evident that the UV-Vis spectra exhibited an increase in absorbency in the visible light region with an increase in Fe concentration. The red shift associated with the presence of Fe ions may be attributed to: i) a charge transfer transition between the Fe ion electrons and the TiO₂ conduction or valence band and/or ii) a dark reddish colour with the increase of Fe concentration [28]. Al/TiO₂ at different Al concentrations absorbed the majority of UV light (less than 400 nm wavelength). Lee et al. [17] also found that Al/TiO₂ by a sol-gel method mainly absorbed UV light in the range of 1 wt% Al – 10 wt% Al. In contrast, when Al/TiO₂ was prepared using a thermal plasma method, the band edge of the powder shifted from UV region to visible light, suggesting that the shift of absorption spectrum should be attributed to the band gap narrowing relating to the interstitial Al species in the TiO₂ crystal [18].
Figure 5 Optical absorbance of a) Fe/TiO$_2$ and b) Al/TiO$_2$ at different concentrations of Fe and Al ions
The photo-catalytic property of Fe/ and Al/TiO₂ was examined under irradiation of UV and visible light for the photodecomposition of gaseous acetaldehyde. The concentration of acetaldehyde was measured by gas chromatography. The major portion of acetaldehyde with Fe/ and Al/TiO₂ was significantly removed under UV irradiation within 60 minutes. The low aluminium concentration Al/TiO₂ led to high photoactivity. However, at high iron concentration (8.3 and 83-Fe/TiO₂), acetaldehyde removal by photo-activity under UV irradiation was nominal. This may be due to high iron concentration. Wang et al. [29] reported that formation of Fe₂O₃ and Fe₂TiO₅ at higher calcination temperature (600 ºC - 800 ºC) resulted in a decrease of photo-catalytic activity. Hung et al. [25] reported that the optimum concentration of iron ions was 0.005% (Fe/Ti) and this enhanced gaseous dichloromethane removal. When the concentration of iron ions was high, the iron ions became recombination centers for the electron-hole pairs and reduced the photo-catalytic activity. Under visible light, the photo-decomposition of acetaldehyde using the Fe/ and Al/TiO₂ was marginal.
Figure 6 Variation of CH$_3$CHO concentration with UV irradiation time (initial concentration of CH$_3$CHO = 2000 mg/L; UV irradiation = black light three 10 W lamps)
CONCLUSIONS

The effect of iron and aluminium on TiO₂ prepared from waste sludge produced by titanium tetrachloride (TiCl₄) flocculation of wastewater was investigated in terms of DOC removal, SEM/EDX, XRD, optical absorbance and photocatalytic activity. The results led to the following conclusions:

1. The removal of organic matter by TiCl₄ flocculation was approximately 70% at 8.5 Ti-mg/L of the optimum concentration.

2. From SEM observation, the majority of Fe/ and Al/TiO₂ particles were found to be less than 1 μm.

3. From EDX results, main elements of Fe/TiO₂ were Ti, O, C, P and Fe and those of Al/TiO₂ were Ti, O, C, P and Al. The sources of C and P atoms were remaining organic carbon from the settled organic matter and nutrient present in wastewater respectively.

4. As iron concentration increased, the atomic percentage of the Fe element in Fe/TiO₂ increased significantly from 0.27 at% (0.083-Fe/Ti) TiO₂ to 9.83 at% (83-Fe/Ti TiO₂). However, as aluminium concentration increased, the atomic percentage of the Al element in AlTiO₂ increased slightly from 0.1 at% (0.038-Al/Ti TiO₂) to 0.46 at% (38-Al/Ti TiO₂). This implied that the FeCl₃ is more favourable coagulant than the Al₂(SO₄)₃ for co-flocculation with TiCl₄.
5. The Fe/TiO$_2$ exhibited majority of the anatase phase. At low iron concentration in TiO$_2$ (0.083-Fe/TiO$_2$ – 8.3-Fe/TiO$_2$), a crystalline phase containing iron atoms ($\alpha$-Fe$_2$O$_3$, Fe$_2$TiO$_5$, etc.) was not observed. However, at 83-Fe/TiO$_2$, hematite (Fe$_2$O$_3$) was found.

6. The Al/TiO$_2$ exhibited the anatase phase only at various aluminium concentrations. A crystalline phase containing Al atoms ($\alpha$-Al$_2$O$_3$, Al$_2$TiO$_5$, etc.) was not observed even at higher Al concentration. This may be due to the low concentration of Al$_2$O$_3$.

7. UV-Vis diffuse reflectance spectra of Fe-TiO$_2$ show an increase in absorbency in the visible light region with the increase in iron ions doping concentration. Al/TiO$_2$ at different Al concentrations absorbed the majority of UV light (less than a 400 nm wavelength).

8. The majority of acetaldehyde with Fe/ and Al/TiO$_2$ was significantly removed under UV irradiation within 60 minutes. Every Al/TiO$_2$ led to high photoactivity. However, at high iron concentration (8.3 and 83-Fe/TiO$_2$), acetaldehyde removal by photoactivity under UV irradiation was very low. This may be due to high iron concentration. Under visible light, the photo-decomposition of acetaldehyde using the Fe/ and Al/TiO$_2$ was marginal.
